2200. Find All K-Distant Indices in an Array

Problem Description

You're provided with an array nums and two integers key and k. The task is to find all indices in the array that are within a distance of k from any occurrence of key in the array. An index i is considered k-distant if there is at least one occurrence of key at index j such that the absolute difference between i and j is less than or equal to k. The challenge is to return all such k-distant indices in ascending order.

The problem focuses on finding these indices efficiently and ensuring that the distance condition (|i - j| <= k) is met for each index related to the key value. In essence, you're creating a list of indices where each index is not too far from any position in the array that contains the key you're interested in.

Intuition

To solve this problem, one straightforward approach is to check each index and compare it with every other index to determine if it meets the k-distance condition with respect to the key.

1. Loop through each index i of the array.

Here are the steps involved in this approach:

- 2. For each index i, loop through the entire array again and check every index j.
- 3. As soon as you find an index j where nums[j] equals key and $|i j| \ll k$, you know that i is a valid k-distant index.
- 4. Add the index i to the answer list (ans) as soon as the condition is satisfied and stop the inner loop to avoid duplicates.
- 5. Once the loops complete, you will have a list of all k-distant indices. 6. Since we begin the search from the start of the array and never revisit indices we've already determined to be k-distant, the resulting list is
- naturally sorted in increasing order.

The Reference Solution Approach provided above implements a brute-force method to identify all k-distant indices. The algorithm

Solution Approach

does not use any complex data structures or patterns but a simple approach to comparing indices with straightforward nested for-loops. Here's an explanation of how the implementation works: We start by initializing an empty list ans that will store our final list of k-distant indices.

- We determine the length of the nums array and store it in variable n, which is used to control the loop boundaries.
- A for-loop runs with \mathbf{i} ranging from 0 to $\mathbf{n} \mathbf{1}$, iterating over each index in the array. For each iteration (for each index \mathbf{i}), we want to check if it is a k-distant index.
- occurrences of key. For every index j, if nums[j] equals key and the absolute difference between i and j (abs(i - j)) is less than or equal to

Inside the outer loop, another for-loop runs with j ranging from 0 to n - 1. This inner loop scans the entire array to check for

k, we've found that index i is k-distant from an occurrence of key. As soon as the condition is met (nums[j] == key and abs(i - j) <= k), we append the current index i to the ans list,

ensuring that each index is only added once due to the break statement that follows the append operation. The break

- ensures the algorithm moves to the next index i once it confirms that i is k-distant. After both loops have completed their execution, the list ans contains all of the k-distant indices. The outer loop's sequential nature guarantees that ans is sorted in increasing order, as indices are checked starting from the smallest i to the largest.
- This solution has a time complexity of $0(n^2)$ due to the nested for-loops each ranging from 0 to n-1. There is no additional space complexity aside from the output array ans, and thus the space complexity is O(n) in the worst case, where n is the

While this brute-force method guarantees a correct solution by exhaustively checking all conditions, it may not be the most efficient for larger arrays due to its quadratic time complexity. Optimizations can be considered using different algorithms or data structures if efficiency is critical.

To illustrate the solution approach, let's consider an example. Suppose we have the array nums = [1, 2, 3, 2, 4], with key = 2 and k = 2.

Example Walkthrough

number of k-distant indices found.

We are tasked with finding all indices in the array that are at most 2 steps away from any occurrence of the number 2. Following the steps of the solution approach:

2. The length of nums is 5 (n = 5). 3. We start an outer loop with i ranging from 0 to 4 (since n - 1 = 4). 4. Now, for each i, we will check every other index j for an occurrence of key that is k-distant.

Let's see how this unfolds step by step:

1. We start with an empty list ans.

the inner loop.

- For i = 0, we check every j. We find that j = 1 satisfies nums[j] = key and abs(i j) <= k(1 0 <= 2), so we add i = 0 to ans and break the inner loop.
- For i = 1, key is present at this same index j = 1 and abs(i j) = 0 which is within k distance, so we add i = 1 to ans and break the

key. Thus, we have successfully found all k-distant indices using the brute-force approach.

inner loop. • For i = 2, the next occurrence of key is at j = 1. The condition nums[1] = key and abs(2 - 1) <= k is true, so add i = 2 to ans and

- break the inner loop. • For i = 3, we find that j = 3 satisfies nums[j] == key as well, and abs(i - j) = 0 is within k distance, so we add i = 3 to ans and break
- For i = 4, the closest key is at j = 3, but $abs(4 3) \ll k$ is true, so we also add i = 4 to ans and break the inner loop.

After the loops complete, our ans list contains [0, 1, 2, 3, 4]. Each index is within a distance of k from an occurrence of the

Solution Implementation

Check if the current element is the 'key' and its index 'j' is within 'k' distance from 'i'

Stop checking other 'j's for the current 'i' as we've found a qualifying 'j'

If the condition is met, add the index 'i' to 'result_indices'

// Return the list of indices that are within distance 'k' from the elements equal to 'key'

// Function to find all indices within 'k' distance from elements equal to 'key'

// Check the distance of current 'i' to all elements in 'nums'

vector<int> findKDistantIndices(vector<int>& nums, int key, int k) {

vector<int> resultIndices; // Vector to store result indices

int n = nums.size(); // Get the size of the input vector

class Solution: def find k distant indices(self, nums: List[int], key: int, k: int) -> List[int]: # Initialize an empty list to store the answer

Loop over each element in 'nums' for i in range(num count): # Loop over the elements in 'nums' again for each 'i' for i in range(num count):

result indices = []

num count = len(nums)

return kDistantIndices;

#include <cstdlib> // Include for std::abs

// Iterate over all elements in 'nums'

for (int j = 0; j < n; ++j) {

for (int i = 0; i < n; ++i) {

Get the length of the input list 'nums'

if abs(i - j) <= k and nums[j] == key:</pre>

result indices.append(i)

Python

```
# Return the list of indices satisfying the condition
        return result_indices
Java
class Solution {
    public List<Integer> findKDistantIndices(int[] nums, int key, int k) {
        // The length of the array 'nums'
        int n = nums.length;
        // Initialize the list to store the answer
        List<Integer> kDistantIndices = new ArrayList<>();
        // Iterate over all elements of 'nums'
        for (int i = 0; i < n; ++i) {
            // Check elements again to find indices within distance 'k' of 'key' in 'nums'
            for (int i = 0; i < n; ++i) {
                // If the absolute difference between indices 'i' and 'j' is less than or equal to 'k'
                // and the current element nums[i] is equal to 'key', the condition is met
                if (Math.abs(i - j) <= k && nums[j] == key) {</pre>
                    // Add the current index 'i' to the list of results
                    kDistantIndices.add(i);
                    // Break from the inner loop since we've found the key at this 'i' index
                    break;
```

C++

public:

#include <vector>

class Solution {

```
// If the absolute difference between indices 'i' and 'j' is less than or equal to 'k'
                // and the element at 'i' is equal to 'kev'
                if (std::abs(i - j) \le k \& nums[j] == key) {
                    resultIndices.push back(i); // Add 'i' to the result indices
                    break; // Stop inner loop since 'i' is within the distance 'k' from an element equal to 'key'
        return resultIndices; // Return the vector with the result indices
};
TypeScript
function findKDistantIndices(nums: number[], key: number, k: number): number[] {
    const numsLength = nums.length; // Holds the length of the nums array
    let distantIndices = []; // Array to store the result
    // Iterate over each element in nums array
    for (let index = 0; index < numsLength; index++) {</pre>
        // Check if the current element is equal to the key
        if (nums[index] === key) {
            // For each element matching the kev, compute the range of indices within k distance
            for (let i = index - k; i <= index + k; i++) {</pre>
                // Ensure the computed index is within array bounds and not already included in the result
                if (i >= 0 && i < numsLength && !distantIndices.includes(i)) {</pre>
                    distantIndices.push(i); // Add the index to the result
    return distantIndices; // Return the array of k-distant indices
```

```
class Solution:
    def find k distant indices(self, nums: List[int], key: int, k: int) -> List[int]:
        # Initialize an empty list to store the answer
        result indices = []
        # Get the length of the input list 'nums'
        num count = len(nums)
        # Loop over each element in 'nums'
        for i in range(num count):
           # Loop over the elements in 'nums' again for each 'i'
            for j in range(num count):
               # Check if the current element is the 'key' and its index 'j' is within 'k' distance from 'i'
               if abs(i - j) \le k and nums[j] == key:
                   # If the condition is met, add the index 'i' to 'result_indices'
                    result indices.append(i)
                   # Stop checking other 'j's for the current 'i' as we've found a qualifying 'j'
                   break
        # Return the list of indices satisfying the condition
        return result_indices
Time and Space Complexity
Time Complexity
```

The given code consists of two nested loops, each iterating over the array nums which has n elements. • The outer loop runs n times for every element i in the array nums.

- For each iteration of i, the inner loop also checks every element j over the entire array.
- When checking the condition if $abs(i j) \ll k$ and nums[j] == key:, it performs constant time checks which can be considered as 0(1).

Hence, the time complexity of the code is 0(n^2) since for each element of nums, the code iterates over the entire nums again.

Space Complexity

The space complexity of the algorithm comes from the list ans which stores the indices. In the worst case, where the condition abs(i - j) <= k and nums[j] == key is true for every element, ans could have the same length as the number of elements in nums. This means that it could potentially store n indices. Therefore, the space complexity is O(n).
