1289. Minimum Falling Path Sum II

Matrix

Dynamic Programming

Problem Description

Array

Hard

non-zero shifts." A falling path with non-zero shifts is a selection of one element from each row of the matrix such that for any two elements chosen from consecutive rows, they are not situated in the same column. Essentially, we need to find a path from the top to the bottom of the matrix, selecting one element from each row, without reusing columns in consecutive rows, and adding those elements to achieve the smallest possible sum. Intuition

Given an n x n integer matrix named grid, the objective is to calculate the minimum sum of what is termed a "falling path with

the second smallest (g) from the previous row. This is because we cannot pick elements from the same column in consecutive rows, so we need to have a backup option in case the smallest value from the previous row is in the same column. The solution progressively calculates the sum of each row, taking into account the smallest sums of the previous row while avoiding the same column positions. For each row, we iterate through its columns and try to find the smallest sum (ff) by either choosing the smallest sum for different columns or the second smallest sum (gg) when the same column as the previous smallest

is encountered. This way, we prevent two consecutive rows from having elements in the same column. By keeping an updated

To find the minimum falling path sum, we can use a <u>dynamic programming</u> approach that builds upon the answer from the

previous row to compute the answer for the current row. Specifically, for each row, we keep track of the smallest value (f) and

minimum (f) and second minimum (g) and their column positions (fp), we can continue to build up the solution row by row, until we reach the bottom of the matrix. The minimum sum of the last calculated row will be the final answer, which provides the minimum sum of a falling path with non-zero shifts as required. **Solution Approach** The solution approach makes use of <u>dynamic programming</u> as its core strategy. The idea is to iterate over each row and compute the minimum and the second minimum values required to reach each position without considering the previous row's column. By doing so, we ensure compliance with the problem's condition that no two elements in adjacent rows are in the same column.

A crucial aspect of the solution is tracking the minimum (f) and the second minimum (g) costs to reach the current row while

recording the column index (fp) of the minimum cost from the previous row. This information is used to decide whether to use

Here's a walkthrough of the algorithm using the problem's terminology: Initialize f and g to 0 as the initial minimum and second minimum costs, respectively. Initialize fp to -1 to indicate no

result.

Example Walkthrough

matrix grid:

[2, 1, 3],

previous column. For each row row in the matrix grid:

 Initialize ff and gg to inf as placeholders for the current row's minimum and second minimum costs. ∘ Initialize ffp to -1, which will hold the column index of the current row's minimum cost. For each value v in row, with its index j: Calculate the sum s by adding v to g if the current column j is the same as fp (to avoid picking two elements from the same column

Assign the value of ff to gg, as ff will now hold the new minimum, s. Update ff with the new minimum, s.

in adjacent rows), or to f otherwise.

If the calculated sum s is less than ff:

- Update | ffp | with the current column index | j |, indicating the column of the new minimum. ■ Else if s is less than gg, update gg with the new second minimum, s.
- After the loop, assign ff to f, gg to g, and ffp to fp for the next iteration. This step effectively moves the minimum and second minimum costs, along with the column index of the minimum, to the next row. Once all rows have been processed, f holds the minimum sum of a falling path with non-zero shifts and is returned as the

programming. In the end, the minimum sum of the final row provides the answer.

Let's use a 3×3 matrix as a small example to illustrate the solution approach.

1. Initialize f and g to 0, and fp to -1 (no previous column):

from the row itself. We then determine f, g, and fp:

Row 1: [6, 5, 4], Previous `fp` = 1

Update `f`, `q`, and `fp` for this row:

5. Repeat the process for the third row:

ff = 13, gg = 15, ffp = 1

Solution Implementation

 $smallest_fall_position = -1$

for row in matrix:

return smallest_fall

for (int[] row : grid) {

public int minFallingPathSum(int[][] grid) {

// Iterating through each row in the grid.

for (int j = 0; j < row.length; ++j) {</pre>

if (sum < curFirstMin) {</pre>

curSecondMin = sum;

minSecondPathSum = newMinSecondPathSum;

return minFirstPathSum; // Return the minimum sum of a falling path.

// Import required modules (if needed in the context where this code will run).

// In vanilla TypeScript, importing modules like this isn't necessary.

// Declare a constant to represent infinity (as a substitute for INT_MAX).

let minFirstPathSum: number = 0; // Stores the minimum sum of the first path.

let minSecondPathSum: number = 0; // Stores the minimum sum of the second best path.

let newMinPathCol: number = -1; // Column index for the new minimum sum.

let prevMinPathCol: number = -1; // Index of the column resulting in the minimum sum in the previous row.

let newMinFirstPathSum: number = kInfinity; // The new minimum sum of the first path.

newMinFirstPathSum = currentSum; // Current sum becomes the new min.

let newMinSecondPathSum: number = kInfinity; // The new minimum sum of the second best path.

newMinSecondPathSum = newMinFirstPathSum; // Previous min becomes second best.

let currentSum: number = (prevMinPathCol !== j ? minFirstPathSum : minSecondPathSum) + row[j];

// If the current sum is less than the new minimum, update both the first and second best sums.

// Global variables acting as state (simulating class member variables)

const n: number = grid.length; // Get the size of the grid.

// Iterate over each element in the current row.

if (currentSum < newMinFirstPathSum) {</pre>

prevMinPathCol = newMinPathCol;

// import { INT_MAX } from 'constants';

for (let row of grid) {

const kInfinity: number = Number.MAX_SAFE_INTEGER;

function minFallingPathSum(grid: number[][]): number {

// Iterate over each row in the input grid.

for (let j = 0; j < n; ++j) {

};

TypeScript

// Prepare for next row.

secondMin = curSecondMin;

firstMinPos = curFirstMinPos;

firstMin = curFirstMin;

Iterate over each row in the matrix.

 $current_smallest_position = -1$

Python

class Solution:

Row 2: [7, 8, 9], Previous `fp` = 2

f = ff = 13, g = gg = 15, fp = ffp = 1

6. After the final row, we update f, g, and fp for the last time:

f = 1, g = 2, fp = 1 (index of minimum value in row 0)

the minimum or second minimum cost when calculating the current row's values.

This solution has a time complexity of $O(n^2)$ where n is the number of rows (or columns) in the matrix, making it efficient enough to handle larger matrices.

The code is a practical implementation of this approach and manifests the described dynamic programming strategy effectively.

Throughout this process, the algorithm avoids using the same column for consecutive rows by considering g (the second

smallest) whenever the current column is the same as the previous row's minimum. By keeping a running tally of the smallest

sums that conform to the problem's rules, the algorithm ensures optimal substructure—one of the hallmarks of dynamic

[6, 5, 4],[7, 8, 9]

Following the dynamic programming approach to find the minimum falling path sum with non-zero shifts:

2. For the first row, since there are no previous rows, the minimum (f) and second minimum (g) sums are the smallest and second smallest values

3. Move to the second row, update ff, gg, and ffp as we find the sums for this row:

ff = 5, gg = 8, ffp = 2

Row 0: [2, 1, 3]

f = 0, g = 0, fp = -1

```
f = ff = 5, g = gg = 8, fp = ffp = 2
```

4. After iterating through the second row, update f, g, and fp with the new values:

For column 0: s = grid[1][0] + g = 6 + 2 = 8 (since column 0 is not `fp`)

For column 2: s = grid[1][2] + f = 4 + 1 = 5 (since column 2 is not `fp`)

For column 1: Cannot choose since `fp` is 1 (same column as the previous minimum)

The minimum sum of a falling path with non-zero shifts is held in f, which is 13 in this case.

Initialize the smallest and second smallest falls from the previous row ("f" and "g").

Initialize the position of the smallest fall in the previous row ("f_position").

Initialize the smallest and second smallest falls of the current row

the smallest fall in the current row ("current smallest_position").

Update the smallest or second smallest fall if necessary.

Move to the next row: update the smallest and second smallest falls and the position

current_smallest, current_second_smallest, current_smallest_position

The matrix has been processed, "smallest_fall" contains the minimum falling path sum.

current smallest = current second_smallest = float('inf')

the previous row to add to the current element.

current second smallest = current_smallest

("current smallest" and "current second smallest"), and the position of

grid[1][2], and grid[2][1], resulting in the path $1 \rightarrow 4 \rightarrow 8$, with a sum of 13.

```
For column 0: s = qrid[2][0] + q = 7 + 8 = 15 (since column 0 is not `fp`)
For column 1: s = grid[2][1] + f = 8 + 5 = 13 (since column 1 is not `fp`)
For column 2: Cannot choose since `fp` is 2 (same column as the previous minimum)
Only two valid sums for this row:
```

This completes the example for the 3×3 matrix, the path that leads to the minimum sum would be from the elements grid[0][1],

total path sum = (second smallest fall if j == smallest fall_position else smallest_fall) + value

final int INF = Integer.MAX VALUE; // Set a high value to represent the initial state that's effectively infinity.

// Calculate the sum by adding the current element to the smaller of the two sums from the previous row,

// but not the one directly above (to avoid falling path through same column, hence j != firstMinPos check).

// If the calculated sum is smaller than the current smallest sum, update the first and second min values and positic

} else if (sum < curSecondMin) { // If the current sum is between first and second min, update the second min only.

Iterate over each value in the current row with its index. for j, value in enumerate(row): # Determine whether to use the smallest or second smallest fall from

if total path sum < current smallest:</pre>

current smallest position = j

current smallest = total path_sum

elif total path sum < current second smallest:</pre>

current_second_smallest = total_path_sum

int firstMin = 0; // The smallest sum of the falling path so far.

int secondMin = 0; // The second smallest sum of the falling path so far.

int curFirstMin = INF; // The smallest sum in the current row.

// Iterating through each element in the current row.

int firstMinPos = -1; // Position of the smallest sum in the previous row.

int curSecondMin = INF; // The second smallest sum in the current row.

int sum = (j != firstMinPos ? firstMin : secondMin) + row[j];

int curfirstMinPos = -1; // Position of the smallest sum in the current row.

curSecondMin = curFirstMin; // The smallest becomes the second smallest.

curFirstMin = sum; // The current sum becomes the new smallest.

curFirstMinPos = j; // Update the current smallest sum position.

smallest fall, second smallest fall, smallest fall position = (

def minFallingPathSum(self, matrix: List[List[int]]) -> int:

smallest fall = second smallest_fall = float('inf')

Java

class Solution {

```

           # Move to the next row: update the smallest and second smallest falls and the position
            smallest fall, second smallest fall, smallest fall position = (
                current_smallest, current_second_smallest, current_smallest_position
       # The matrix has been processed, "smallest_fall" contains the minimum falling path sum.
       return smallest_fall
```

Time Complexity The time complexity of the code is O(n * m), where n is the number of rows and m is the number of columns in the input grid.

Time and Space Complexity

This is because the code iterates through each row with an outer loop and each column with an inner loop, computing the minimum falling path sum in a single pass. **Space Complexity**

The space complexity of the code is 0(1). Although the algorithm iterates through the entire grid, it uses only a constant amount

of additional space for the variables f, g, fp, ff, gg, and ffp, regardless of the size of the input grid.
