2186. Minimum Number of Steps to Make Two Strings Anagram II

Leetcode Link

Problem Description

In this problem, we are given two strings s and t. The task is to perform a series of steps with the goal of making these two strings anagrams of each other. An anagram is a rearrangement of letters to form a different word or phrase, typically using all the original letters exactly once; for example, 'listen' is an anagram of 'silent'.

The only allowed action in each step we can take is to append any character we want to the end of either string s or string t. The main objective is to determine the fewest number of such steps required to make the strings anagrams of each other. There is no restriction on how many times a character can be added, and there is no need to add the same character to both strings.

Intuition

same amounts to be anagrams of each other, what we ultimately need to do is to balance out the character counts in both strings. To find the minimum number of steps required, we should:

The intuition behind the solution comes from the definition of an anagram. Since both s and t must have the same characters in the

1. Count the frequency of each character in string s. This is because we need to know how many of each character we have to

- begin with and what we may need to add to to balance the two strings. 2. Subtract the frequency of each character that appears in t from the frequency count obtained from s. When we do this, the
- 3. To make s and t anagrams of each other, we need to make up for the character deficits between the two strings in other words, we need to convert the negative counts to zero by appending characters to t, and reduce the positive counts to zero by

count for a character will increase if t has fewer instances of that character than s, decrease if t has more of that character, or

remain the same if both have an equal number. This gives us a measure of the deficit or surplus of characters in t relative to 5.

- appending characters to s. We don't actually append the characters; we just need to count how many characters would need to be appended. 4. We sum the absolute values of these counts, which gives us the total number of characters that need to be added to either string; in other words, the minimum number of steps required to make the strings anagrams.
- The given solution achieves exactly this with an efficient approach utilizing the Counter from Python's collections module to tally the characters quickly and a loop to adjust the counts based on the second string t.

Solution Approach

The solution uses the Counter class from Python's collections module, which is a subclass of dict. It is designed to count objects, a

special data structure that is ideal for tallying a hashable object (in our case, the characters in the string s).

Here's how the implementation works step by step:

1. cnt = Counter(s): We instantiate a Counter object for the first string s. This counts the frequency of each character in s and stores it as key-value pairs, where the key is the character, and the value is the number of times that character occurs in s.

2. for c in t: cnt[c] -= 1: We iterate over each character c in the second string t. For every character, we decrement its count

representing a surplus of that character in t. If t has fewer of that character, the count for that character will either decrease towards zero (if s had more initially) or stay negative. 3. return sum(abs(v) for v in cnt.values()): After adjusting the counts based on both strings, we compute the sum of the

absolute values of these counts. This is because we want the total number of characters that are in surplus or deficit—

in the Counter by one. If t has more of a particular character than s, the count for that character will become negative,

regardless of the string to which they need to be added—to make s and t anagrams. As explained in the intuition, negative counts indicate a surplus in t (and thus a need to add characters to s), while positive counts indicate a surplus in s (and a need to add characters to t). The absolute value treats both cases the same way, as simply characters to be added. The use of abs() function in step 3 is crucial because we want to ignore whether the final count is positive or negative for our purpose. We are only interested in how many characters in total are out of balance.

absolute differences in character counts between the two strings.

calculations in a condensed manner without the need for lots of loops or conditionals, and the final result is simply the sum of

This approach offers an efficient and straightforward solution to the problem: it leverages Python's Counter to handle the

Example Walkthrough Let's walk through a small example using the solution approach described above. Suppose we have s = "abc" and t = "xabc" as our strings, and we want to make them anagrams of each other.

1. Count the characters in s: First, we will create a Counter object for string s. After this step, cnt will look like {'a': 1, 'b': 1,

Using the solution approach:

o cnt['a'] will be 1 - 1 = 0

o cnt['b'] will be 1 - 1 = 0

'c': 1} since these are the frequencies of the characters in s.

other characters exactly once, cnt will be updated like this:

2. Adjust counts based on t: Next, we'll iterate through the second string t and update the counts in our Counter object. For each character in t, we will decrease the corresponding count in cnt. After processing t, which has x that doesn't exist in s and all the

o cnt['c'] will be 1 - 1 = 0 ○ cnt['x'] will be 0 - 1 = -1 (since 'x' was not in s to begin with, it starts at zero and gets decreased) 3. Compute the number of steps needed to make s and t anagrams: After the second step, our counter cnt shows that s and t

are already anagrams for characters a, b, and c (because their counts are 0), but we have an extra 'x' in string t that needs to be

balanced. Thus, cnt is {'a': 0, 'b': 0, 'c': 0, 'x': -1} now. We are interested in the sum of the absolute values of the

```
counts:
      \circ abs(0) + abs(0) + abs(0) + abs(-1) = 0 + 0 + 0 + 1 = 1
So, in this example, only 1 step is required to make s and t anagrams of each other, and that step is to append an 'x' to s.
```

Example Walkthrough showing how one would apply the solution to a real-world example.

Decrease the count in the Counter for every character in string t

// Sum the absolute values of the differences in character counts

// Return the total number of steps to make t an anagram of s

Sum the absolute values of the counts in the Counter.

Create a Counter object for the string s to keep track of character frequencies

Python Solution from collections import Counter class Solution: def minSteps(self, s: str, t: str) -> int:

This approach highlights the power of using a Counter object to efficiently tackle this problem and provides a simple and clear

This gives the total number of characters that are different 13 # between s and t, which is the number of steps required. 14 15 return sum(abs(value) for value in char_count.values()) 16

Time and Space Complexity
```

The time complexity of the provided code is derived from iterating over both strings s and t and the summation of the values in the

Time complexity

part is O(m).

counter cnt. 1. cnt = Counter(s): Creating a counter for string s has a time complexity of O(n) where n is the length of string s.

3. The summation sum(abs(v) for v in cnt.values()): This operation is dependent on the number of unique characters in s. In the worst case, each character is unique, and the complexity of this summation would be O(u), where u is the number of unique

2. The for-loop iterating over string t: The loop runs for the length of string t, which is m. Therefore, the time complexity for this

- characters, which is at most n. Summing up, if n is the length of string s and m is the length of string t, the total time complexity is 0(n + m + u). Since $u \ll n$, we
- can simplify this to O(n + m).

Space complexity The space complexity is mainly due to the storage required for the counter cnt.

- 1. cnt = Counter(s): The counter for string s needs space for each unique character. In the worst case, this is O(u) where u is the number of unique characters in s, which is at most n characters.
- Thus, the space complexity of the algorithm is O(u), and considering $u \ll n$, it simplifies to O(n).
