## 2430. Maximum Deletions on a String Rolling Hash

In this problem, you are given a string s that consists only of lowercase English letters. Your task is to determine the maximum number of operations you can perform to delete the entire string. There are two types of operations you can perform:

**Leetcode Link** 

1. Delete the entire string at once.

**Problem Description** 

2. Delete the first i letters of the string if and only if the first i letters are exactly the same as the next i letters. This can be done for any i satisfying  $1 \ll i \ll s$ . length / 2.

because the first two letters ("ab") and the two following letters ("ab") are equal. This will leave you with the string "abc".

For example, let's assume you have the string s = "ababc". In one possible operation, you can delete the first two letters ("ab")

The goal is to return the maximum number of operations that can be applied to delete all of s.

Intuition

## To solve this problem, one approach is to use dynamic programming to break down the problem into smaller, more manageable

function dfs(i) is defined to determine the maximum operations that can be performed starting from the i-th character of the string up to the end. The key intuition for the solution is as follows:

• If we are at the end of the string (index i is equal to n, the length of the string), there are no operations left to perform, hence

subproblems. With dynamic programming, you can determine the optimal sequence of operations for each substring. The recursive

the base case of the recursion is dfs(i) = 0. • For any position i in the string, we try to find any index i + j such that s[i : i + j] is equal to s[i + j : i + 2 \* j], which

- means we can perform an operation to delete s[i : i + j]. • For each valid j where a deletion can be performed, we recursively solve the problem for the remainder of the string starting
- from index i + j. • We use memoization (cache) to remember the results of subproblems we've already solved to avoid redundant calculations and
- improve efficiency. • The final answer is the maximum number of operations we can perform, which is the best result out of all possible deletions from
- **Solution Approach**
- The solution makes use of dynamic programming and recursion to solve the problem. Dynamic programming is an optimization

technique that solves problems by breaking them down into simpler subproblems and storing the results (usually in an array or hash

# Here's how the implementation works:

index i.

index i. This helps us in breaking down the larger problem into smaller ones. 2. The base case of our recursion occurs when i reaches n, the length of s, meaning that there is no more string left to delete. In this case, dfs(i) returns 0 because no operations can be performed.

1. We define a recursive function dfs(i) which computes the maximum number of operations that can be performed starting from

instead of recomputing it.

Example Walkthrough

following string of the same length.

table) to avoid redundant computations.

- 3. For any given index i, we iterate through all possible values of j such that 1 <= j <= (n i) / 2. These values represent potential cut points where we can split the string and perform a delete operation if the substring can be matched with the
- 4. During the iteration, we check if the substring s[i : i + j] is equal to s[i + j : i + 2 \* j]. If they are equal, we can delete s[i:i+j]. We then call dfs(i+j) to find out how many more operations can be performed starting from index i+j.

5. We use the max function to keep track of the maximum number of operations that we can perform. The variable ans is updated

with 1 + dfs(i + j) if a match is found since we have performed one operation plus however many more we can perform from the new starting point. 6. To ensure the solution is efficient, we use the @cache decorator from Python's functools module for memoization. This stores

the result of dfs(i) the first time it is computed for any index i, and subsequent calls with the same i will use the cached result

operations for the entire string is returned. By caching intermediate results, the implementation ensures that each subproblem is solved only once, leading to a significant performance improvement, particularly for larger strings. This is a common optimization in dynamic programming solutions to reduce

7. At the end, the function dfs(0) is called to kick off the recursion from the beginning of the string, and the maximum number of

Let's use the string s = "aabbcc" to illustrate the solution approach. 1. We start by defining the recursive function dfs(i) to find the maximum number of operations starting from index i.

3. At index 0, we have the whole string s = "aabbcc" to work with. We look for j's where 1 <= j <= (n - i) / 2 which translates to

## 4. For j = 1, we check if s[0 : 1] ("a") is the same as s[1 : 2] ("a"). They match, so we can perform a delete operation. We also call dfs(1) to find the maximum number of operations from s = "abbcc".

from functools import lru\_cache

@lru\_cache(None)

answer = 1

length = len(string)

maxDeleteWays[i] = 1;

return maxDeleteWays[0];

for (int j = 1;  $j \le (n - i) / 2$ ; ++j) {

if (longestPrefix[i][i + j] >= j) {

return dfs(0)

 $1 \ll j \ll 3$  for our string.

here as well.

the time complexity from exponential to polynomial.

5. Now, inside dfs(1), we repeat the process. We find that there are no j values that allow us to perform a delete operation, so dfs(1) returns 0.

to delete the string s = "aabbcc", with the final answer being 1.

def deleteString(self, string: str) -> int:

def dfs(index: int) -> int:

# Use lru\_cache to memoize previously computed results

for j in range(1, (length - index) // 2 + 1):

# Get the length of the string to avoid recalculating it

# Begin the dfs from the start of the string

answer = max(answer, 1 + dfs(index + j))

// Try to delete every possible substring length starting at i

// Result is the maximum number of deletions starting from first character

// If the current substring can be deleted (found in its continuation)

// Update f[i] if deleting substring leads to more delete operations

maxDeleteWays[i] = Math.max(maxDeleteWays[i], maxDeleteWays[i + j] + 1);

# Try to find a duplicated substring starting at the current index

if string[index : index + j] == string[index + j : index + 2 \* j]:

- 6. Since dfs(1) returns 0, the maximum operations for j = 1 at i = 0 is 1 + dfs(1) which equals 1. 7. Next, we try j = 2. We find that s[0 : 2] ("aa") is the same as s[2 : 4] ("bb"), which do not match, so we cannot perform a
- delete operation for this j.

2. We call dfs(0) because we want to start from the beginning of the string.

9. Since only j = 1 allowed us to perform an operation, the answer from dfs(0) is 1, which we've previously calculated. 10. No more operations can be performed, so the max number of operations for the entire string is 1.

11. Using memoization with the @cache decorator, if dfs(1) was called again, it would immediately return 0 without recomputation.

This recursion and memoization process allows us to efficiently calculate the maximum number of operations that can be performed

8. Finally, we try j = 3, and find that s[0 : 3] ("aab") is not equal to s[3 : 6] ("bcc") so we cannot perform a delete operation

**Python Solution** 

# If we've reached the end of the string, there's no more to delete, so return 0 if index == length: return 0 10 # Initialize answer at 1, as there's at least the possibility of deleting the current character 12

# Take the max of the current answer and 1 (for this deletion) + the result of dfs from the next index

# If a duplicate is found, recursively call dfs from the end of this duplicate substring

```
21
22
               # Return the maximum number of deletions that can be made from this index
23
                return answer
24
```

Typescript Solution

function deleteString(s: string): number {

const lengthOfString = s.length;

// Get the length of the input string.

// Iterate over the string in reverse.

for (let  $i = length0fString - 1; i >= 0; --i) {$ 

const maxDeletes: number[] = new Array(lengthOfString).fill(1);

## **Time Complexity** The provided code uses a recursive function dfs that explores the possibilities of splitting the string into two equal parts and

return maxDeletes[0];

Time and Space Complexity

done once, rather than being recomputed multiple times.

Considering that n is the length of the string s, the recursion could run theoretically for each starting position i and try to match substrings of length j, which can range from 1 to (n - i) / 2. Therefore, in the worst-case scenario where the function checks all possibilities, it would make 0(n/2) comparisons for each i. And since this is done for each i, the overall time for comparisons is

checking if they are the same, then recursively applying the same logic to the rest of the string.

// Initialize an array to store the maximum number of identical contiguous substrings from each position.

// Return the maximum number of identical contiguous substrings that can be deleted from the entire string.

// Try to match substrings of all possible lengths starting from the current position.

Moreover, due to the use of memoization (indicated by @cache), each state dfs(i) is only computed once, which reduces the number of recursive computations from what would be exponential in the recursive case to linear in the number of unique states. Given that the states correspond to the starting indices of the string s, there are n unique states. Hence, the memoization does not change the number of comparisons per se, but it does ensure that each state calculation is only

Thus, the time complexity, which involves the nested iteration and memoization, is 0(n^3/2) because for each i, you could perform 0(n/2) comparisons and this is done for n different starting positions. Hence, the final time complexity is  $0(n^3)$ .

**Space Complexity** 

The space complexity of the code is influenced by the maximum size of the recursion stack and the space used by the cache to store results of previous computations.

- 1. Recursion Stack: In the worst-case scenario, the recursion can go as deep as the length of the string s, which is n. Thus, the recursion stack could potentially take up O(n) space.
- 2. Cache: Since the cache stores the results for each unique state (i), and there are n possible unique states, the space complexity for memoization is also O(n).

Therefore, the total space complexity is the sum of the recursion stack and the cache, which gives us 0(n) + 0(n). However, since we drop constants in Big O notation, the space complexity simplifies to O(n).
