1292. Maximum Side Length of a Square with Sum Less than or Equal to Threshold

Prefix Sum Leetcode Link

Given a matrix of integers mat with dimensions m x n and an integer threshold, the task is to find the maximum side length of a

Problem Description

square submatrix where the sum of its elements is less than or equal to threshold. If no such square exists, we should return 0. The problem challenges us to do this efficiently across all possible submatrices in a large matrix.

Intuition To solve this problem, we use dynamic programming to precompute the sums of submatrices to quickly assess whether a square of

a given size meets the threshold criteria. The intuition behind the approach is to use a binary search algorithm to efficiently find the

First, we create an auxiliary matrix s where each element s[i][j] represents the sum of elements in the rectangle from the top-left corner of the matrix to (i, j). This auxiliary matrix allows us to compute the sum of any submatrix in constant time by using the inclusion-exclusion principle.

The binary search is done on the side length of the square. For each possible side length k, we use the auxiliary matrix to check if

maximum side length, combined with a sum lookup that leverages the precomputed sums of submatrices.

there exists at least one square submatrix of size k x k with a sum less than or equal to threshold. If such a square exists for a side length k, we know that any smaller square will also satisfy the condition, so we continue the search for larger squares. If there is no such square, we decrease the side length and continue the search. This process is repeated until we narrow down to the maximum

square size that satisfies the sum condition. By combining binary search for efficiency and dynamic programming for fast submatrix sum calculation, the algorithm efficiently

solves the problem without checking every possible square individually, which would be computationally expensive. Solution Approach The provided solution leverages dynamic programming and binary search to find the maximum side-length of a square with a sum

Dynamic Programming

To calculate the sum of any submatrix quickly, an auxiliary matrix is is created. This 2D array stores the cumulative sum for every

The sum for each element s[i][j] is obtained by:

This formulation is based on the inclusion-exclusion principle, where s[i - 1][j] + s[i][j - 1] adds the rectangle above and to the left of (i, j), but since the intersection (mat[0][0] to mat[i - 1][j - 1]) is added twice, it is subtracted once with - s[i - 1]

Binary Search

Within each iteration of binary search:

and width, as this represents the largest potential square.

less than or equal to the provided threshold.

index (i, j) representing the sum of elements from (0, 0) to (i, j).

1 s[i][j] = s[i-1][j] + s[i][j-1] - s[i-1][j-1] + mat[i-1][j-1]

[j-1]. Finally, mat[i-1][j-1] is added to include the current cell.

4. If no such square exists for mid, the upper half (r) is updated to mid - 1.

5. The binary search loop continues until 1 is no longer less than r.

the overhead of calculating every possible square sum independently.

First, we build the auxiliary matrix s to store cumulative sums:

1. The first mid value is (0 + 3) / 2 = 1.5, rounded down to 1.

all values from the original matrix qualify, as they are all less than 8.

3. Since check(1) is true, we update left = mid + 1, and the new range becomes 2 to 3.

2. We call check(2) for each possible 2x2 square. For instance, for the top-left 2x2 square:

```
Binary search is used to find the maximum valid square side length. The search range is from 0 to the minimum of the matrix's height
```

1. The middle of the current range (mid) is selected as the candidate side-length for the square. 2. A check function, check(k), is called to verify if there exists at least one $k \times k$ square whose sum is within threshold. 3. If such a square exists for mid, the lower half (1) of the search is updated to mid, as we want to continue searching for possibly larger squares that satisfy the condition.

The check(k) function iterates over all possible positions for the top-left corner of a k x k square. It uses the previously computed

auxiliary matrix s to determine if the sum of the square is less than or equal to threshold by performing a simple subtraction

operation that removes the unnecessary areas, similar to how s was populated. $1 \ v = s[i + k][j + k] - s[i][j + k] - s[i + k][j] + s[i][j]$

Time Complexity

0(m * n) time.

- The overall time complexity of the solution is $O(m * n * \log(\min(m, n)))$, where m and n are the dimensions of the input matrix. This is due to the binary search varying between 1 and min(m, n) and the sum check performed within the check(k) function that takes
- Example Walkthrough

Let's illustrate the solution approach using a small example. Suppose we have the following 3×3 matrix mat and a threshold of 8:

As a result, the solution is efficient and effective, providing a fast way to compute the largest square within threshold while avoiding

[7, 8, 9]

Each element s[i][j] represents the sum of elements from (0, 0) to (i-1, j-1) in the original matrix.

We want to find the maximum side length of a square submatrix where the sum of its elements is less than or equal to threshold.

[0, 12, 27, 45]

[1, 2, 3],

[4, 5, 6],

1 mat = [

Next, we use binary search to find the maximum side length of the square. We start the search with left = 0 and right = min(m, n) = 3.

2. We call check(1) for each possible 1x1 square and see if any square's sum is less than or equal to the threshold. For 1x1 squares,

```
We repeat this process:
 1. Our next mid is (2 + 3) / 2 = 2.5, rounded down to 2.
```

The check function, which checks if a square with side k has a sum less than or equal to the threshold, is 0(m * n) as well for each individual k, since, in the worst case, it has to iterate over the entire matrix again, checking each possible top-left corner of a square. Finally, the binary search performed in the last part of the code runs in O(log(min(m, n))) time. Since the binary search calls the check function at each iteration, the combined time complexity for the search routine with subsequent checks is 0(m * n *

log(min(m, n))). Hence, the overall time complexity of the code is $0(m * n + m * n * \log(\min(m, n)))$ which simplifies to $0(m * n * \log(\min(m, n)))$ n))).

The provided code operates in several steps. The computation of the prefix sum matrix, s, takes 0(m * n) time where m is the

number of rows and n is the number of columns in the input matrix, mat. This is because it needs to iterate over every element in mat

Regarding space complexity, the additional space is used for the prefix sum matrix, s, which has dimensions $(m + 1) \times (n + 1)$.

Therefore, the space complexity is 0((m + 1) * (n + 1)), which simplifies to 0(m * n) since the +1 is relatively negligible for large m
