## 2961. Double Modular Exponentiation

Medium <u>Array</u> **Math** Simulation

## **Problem Description**

c\_i, m\_i]. In addition, you are provided with an integer target. An index i in the variables array is considered good if it satisfies a certain mathematical condition based on the values of a\_i, b\_i, c\_i, and m\_i. The condition is that the expression ((a\_i^b\_i % 10)^c\_i) % m\_i must be equal to the target. Here the ^ represents exponentiation, and % is the modulo operation. The task is to identify all the indices that are *good* and return them as an array in any order. An index is *good* if the above formula

In this problem, you are given a two-dimensional array named variables where each element is a list of four integers [a\_i, b\_i,

matches the target when evaluated with the values at that index in the variables array. You need to consider each index i from 0 to variables.length - 1 and check the formula for each. Intuition

## The intuition behind the solution lies in understanding how modulo arithmetic can be used to simplify calculations and the properties of exponents. Since the final expression involves taking $a_i$ to the power of $b_i$ , then to the power of $c_i$ , and applying

m\_i.

modulo m\_i to check if it equals the target, we can take advantage of the following properties: Exponentiation by Squaring (Fast Power Method): This method allows us to compute a^b efficiently by squaring and reducing the number of multiplications we need to perform. This is especially useful when b is very large.

- Modulo Properties: We can use the property (a \* b) % m = ((a % m) \* (b % m)) % m, which states that the result of a product modulo m is the same regardless of whether we perform the modulo before or after multiplication. We can also apply
- this principle to exponentiation.

The solution applies the Python pow function, which takes an additional modulo argument, making these operations

By applying these optimizations, we can effectively reduce the calculations needed to verify whether an index i satisfies the condition. Hence, the process for each index i is to apply the modulo operation as soon as possible during the exponentiation steps to keep the numbers manageable and prevent overflow. This is done by calculating a^b % 10 and then ((a^b % 10)^c) %

straightforward and efficient. By doing so, we loop through each variables[i] and apply the property (a^b % 10)^c % m\_i and compare it to the target. If it matches, we add the index i to our output list. This approach is both clean and efficient, allowing us to handle even large powers effectively. Solution Approach

The implementation of the solution uses a relatively simple approach aligned with the properties of modulo arithmetic and exponentiation. Here's how it works: **Iteration**: We iterate through each index i of the input variables array using a for-loop.

## **Exponentiation**: For every tuple (a, b, c, m) at index i, we need to calculate the expression ((a^b % 10)^c) % m and check

class Solution:

if it equals the target. **Exponentiation with Modulo:** The Python pow function is perfect for this task because it allows us to efficiently calculate

powers with a modulo. The regular power operation a^b may lead to very large numbers, especially when b and c are large, which is computationally expensive and can cause integer overflows. However, by using the pow function with a modulo, we

can calculate a^b % 10 much more quickly and safely.

pow(result, c, m) where result is a^b % 10.

- The first power operation is pow(a, b, 10) which computes a^b % 10. We modulo by 10 because exponentiation modulo 10 gives us the last digit of a^b, which is all we need for the next power. The resulting number then needs to be exponentiated again with c and taken modulo m. This is continued with another pow operation -
- Check Against Target: The final result of the nested pow function is compared to the target. If they match, the index i is considered *good*. Building the Output List: The indices where the condition holds true are gathered into a list using a list comprehension. This list is returned as the final output.
- squaring) is implicitly applied through Python's built-in pow function with mod argument, as this is a known efficient way to compute powers in modular arithmetic.

The process uses a direct simulation of the problem's formula. The fast power method (also known as exponentiation by

return [ for i, (a, b, c, m) in enumerate(variables) if pow(pow(a, b, 10), c, m) == target

In the provided code, enumerate(variables) gives us both the index i and the list [a, b, c, m]. For each index and list, if

pow(pow(a, b, 10), c, m) == target evaluates the condition. If the condition is true, the i is included in the output list. This is

**Example Walkthrough** 

**Step 1**: We start by iterating over each index in the variables array.

• The result is 0, which does not match the target of 1. Hence, index 0 is not good.

For index 1: The tuple is [3, 2, 2, 3], representing a=3, b=2, c=2, m=3.

• We calculate 2<sup>3</sup> % 10, which is 8 % 10 giving us 8.

We calculate 3<sup>2</sup> % 10, which is 9 % 10 giving us 9.

• We calculate 2<sup>5</sup> % 10, which is 32 % 10 giving us 2.

The solution code using this approach would be:

of *good* indices would be empty - [].

Next, we calculate (8<sup>1</sup>) % 4, which is simply 8 % 4 giving us 0.

Here's a breakdown of the algorithm based on the solution code:

```
Let's work through a small example to illustrate the solution approach.
  Assume we have the following variables array and the target value:
variables = [
    [2, 3, 1, 4], # Index 0
    [3, 2, 2, 3], # Index 1
    [2, 5, 2, 1], # Index 2
```

an elegant and effective way to solve the problem with minimal code and high readability.

def getGoodIndices(self, variables: List[List[int]], target: int) -> List[int]:

For index 0: The tuple is [2, 3, 1, 4], representing a=2, b=3, c=1, m=4.

target = 1

 Next, we calculate (9<sup>2</sup>) % 3, which is 81 % 3 giving us 0. • The result is 0, which does not match the target of 1. Hence, index 1 is not good.

We need to find all indices where the condition  $((a_i^b_i % 10)^c_i) % m_i == target holds true.$ 

 Next, we calculate (2<sup>2</sup>) % 1, which is 4 % 1 giving us 0. • However, since any number modulo 1 is 0, this does not match our target of 1. Hence, index 2 is not good.

For index 2: The tuple is [2, 5, 2, 1], representing a=2, b=5, c=2, m=1.

class Solution: def getGoodIndices(self, variables: List[List[int]], target: int) -> List[int]: return

computations and avoid overflow, while checking each index against the target.

def get\_good\_indices(self, variables: List[List[int]], target: int) -> List[int]:

if pow(pow(variable[0], variable[1], 10), variable[2], variable[3]) == target

# where 'i' is the index and 'variable' is a list [a, b, c, m]

for i, (a, b, c, m) in enumerate(variables)

if pow(pow(a, b, 10), c, m) == target

# Iterate over the list enumerating the variables

# result = solution.get\_good\_indices([[2, 3, 1, 10], [3, 3, 2, 12]], 8)

public List<Integer> getGoodIndices(int[][] variables, int target) {

// Extract individual variables from the current set.

if (quickPow(quickPow(a, b, 10), c, m) == target) {

long long result = 1; // Start with a result of 1

if (exponent & 1) { // Check if the current bit is 1

while (exponent > 0) {

# print(result) # Output: list of indices that match the criteria

// Iterate over each variable array.

int a = variableSet[0];

int b = variableSet[1];

int c = variableSet[2];

int m = variableSet[3];

goodIndices.add(i);

int[] variableSet = variables[i];

Solution Implementation

The code works efficiently through the properties of exponents and modulo arithmetic, using Python's pow function to simplify the

At the end of the iteration, unfortunately, no indices satisfy the condition for our small example, and therefore the resulting array

return [ for i, variable in enumerate(variables) # Check if the complex power expression matches the target # a raised to the power of b mod 10, raised to the power of c mod m should equal target

```
for (int i = 0; i < variables.length; ++i) {</pre>
```

Java

**Python** 

from typing import List

class Solution:

# Example usage:

class Solution {

# solution = Solution()

```
return goodIndices; // Return the list of indices.
    // Method to compute (a^b) % mod quickly using binary exponentiation.
   private int quickPow(long a, int n, int mod) {
        long result = 1; // Initialize result to 1.
       // Loop until n is zero.
        for (; n > 0; n >>= 1) {
           // If the current bit in n is set, multiply result by 'a' and take mod.
           if ((n & 1) == 1) {
                result = (result * a) % mod;
           // Square 'a' and take mod to use for the next iteration.
            a = (a * a) % mod;
        return (int) result; // Cast the long result back to int and return.
C++
#include <vector>
class Solution {
public:
    // Function to find all the indices of variables that meet a certain condition.
    std::vector<int> getGoodIndices(std::vector<std::vector<int>>& variables, int target) {
        std::vector<int> goodIndices; // This will store the indices that meet the condition
       // Lambda function for fast exponentiation under modulo (to avoid integer overflow)
       auto fastPowerModulo = [&](long long base, int exponent, int modulo) -> int {
```

// Continuously square base and multiply by base when the exponent's current bit is 1

result = (result \* base) % modulo; // Multiply by base and take modulo

base = (base \* base) % modulo; // Square the base and take modulo

exponent >>= 1; // Shift exponent right by 1 bit (divide by 2)

// Method to find all the indices in 'variables' array where the recursive power operation result equals 'target'.

class Solution:

# Example usage:

# solution = Solution()

# result = solution.get\_good\_indices([[2, 3, 1, 10], [3, 3, 2, 12]], 8) # print(result) # Output: list of indices that match the criteria

# a raised to the power of b mod 10, raised to the power of c mod m should equal target

if pow(pow(variable[0], variable[1], 10), variable[2], variable[3]) == target

pow function used inside the list comprehension. The pow function in Python has a time complexity of O(log n), where n is the exponent. Here, the pow function is used twice; the first call executes pow(a, b, 10), and the second call executes

The time complexity of this code is primarily dependent on the enumerate function that iterates through the variables list and the

Considering M as the maximum value among all values of b\_i and c\_i, and with M being limited to 10^3 in the problem, the time complexity per iteration is 0(log M). Since there are n elements in variables, where n is the length of variables, the total time complexity is O(n \* log M).

pow(result\_of\_first\_call, c, m). Since b and c are the exponents used in each call, the time complexity for each iteration is

The space complexity of the code is 0(1) because the extra space required is constant and does not depend on the input size. There are no additional data structures that grow with the size of variables. The list comprehension simply produces the final list of indices, which the function returns and does not count towards extra space as it is the required output.
