## 1915. Number of Wonderful Substrings

#### Medium String Bit Manipulation Hash Table Prefix Sum

## Problem Description

of times. We are tasked with counting the number of wonderful non-empty substrings within a given string word. This string word contains only the first ten lowercase English letters ('a' through 'j'). It is important to note that we must consider each occurrence of a wonderful substring separately even if it appears multiple times in word. A substring is defined as a contiguous sequence of characters within a string.

The problem presents a concept of a 'wonderful' string which is defined as a string where at most one letter appears an odd number

Leetcode Link

## The intuition behind solving this problem lies in recognizing patterns and efficiently tracking the frequency of characters as we

Intuition

consider different substrings. A naive approach would be to check all possible substrings and count how many meet the criteria, but this would be too slow for larger strings. The solution uses bitwise operations to keep track of the frequency of each letter in a space-efficient manner. We can represent the

frequency of each of the 10 letters by a single bit in an integer (st). If a letter appears an even number of times, its corresponding bit

is set to 0, and if it appears an odd number of times, its bit is set to 1. The wonderful property is then satisfied if at most one bit is set to 1 in this integer. We initialize a counter to keep track of the occurrences of each bit pattern as we iterate through word. As we consider each new character, we update our bit pattern state st. For each new character, we add to our answer the count of the current state st to

capture the same pattern we have already seen (which automatically represents an even number of each letter in the substring). Additionally, we iterate through each bit position to flip it, checking if there is a pattern that had all bits even except for the current one. This would represent substrings with all even counts of characters except one, meeting the 'wonderful' criteria. The Counter structure is used to keep track of how many times we've encountered each bit pattern. This allows us to quickly calculate the new number of wonderful substrings each time we process a new character in the string. By adding the counter for the

current state and the counter for states with one bit flipped, we can account for all the substrings that end at the current character

Using this method, we efficiently compute the number of wonderful substrings in the given word without checking every possible substring individually. Solution Approach

The solution implemented in the reference code uses a combination of bit manipulation, hashing (via a Counter dictionary), and comprehension of the property of wonderful substrings.

1. Bit Manipulation: To track the odd or even frequency of each letter without storing the counts individually, the solution uses bit

#### manipulation, where each bit in a state integer st represents the count of a particular letter from 'a' to 'j'. The least significant bit corresponds to a, the second least significant bit to b, and so on up to the tenth bit for j. If a letter has appeared an odd

Counter class.

the sum of:

and are wonderful.

number of times, the corresponding bit is set to 1, and if it has appeared an even number of times, it's set to 0. 2. Counter Dictionary: This is used to hash the number of times each bit pattern appeared. It's implemented using Python's

3. State Transition: When a new character from the string word is processed, we calculate the new state st by using the XOR

operation st ^= 1 << (ord(c) - ord("a")). The XOR operation with 1 shifted left by (ord(c) - ord("a")) positions flips the bit corresponding to the new character. This changes the bit from 0 to 1 if the character count was even (representing an odd count now) and from 1 to 0 if the count was odd (representing an even count now). 4. Counting Wonderful Substrings: The number of wonderful substrings that can be formed ending with the current character is

The number of times the current state st has been seen before, which is ans += cnt[st], because if we've seen this pattern

 The number of times each bit-flipped state has occurred, which is computed with ans += cnt[st ^ (1 << i)] for i in</li> range (10). Flipping each bit simulates having all the other letters appear an even number of times and only one letter an odd number of times, which is still a 'wonderful' state.

before, it means there is a substring ending here that maintains the evenness of all previously processed characters.

The solution goes through each character only once, and for each character, it checks 10 possible states—those with no letters appearing an odd number of times and those with exactly one. This results in a linear 0(n\*10) solution, where n is the length of word.

5. Updating the Counter: After accounting for the new wonderful substrings, cnt[st] += 1 updates the count for the current state.

In terms of space complexity, the counter keeps track of at most 2^10 (1024) different bit patterns, which corresponds to a bitwise representation of letter counts. So the space complexity is 0(2<sup>k</sup>) where k is the number of unique letters, which is 10 in this case. However, it only keeps track of bit patterns that have been seen, so the actual space used could be much less.

which means all bits are set to 0, indicating even counts of all letters. 2. Counter Dictionary: We initialize a Counter with cnt = {0:1}, which implies we have already encountered a state with all even counts once (an empty substring).

1. Bit Manipulation: We are using bit manipulation to track the frequency of each letter using the state integer st. Initially, st = 0,

#### Process the first character 'a': The state transition is st ^= 1 << (ord('a') - ord('a')), hence st = 0b0000000001. The</li> Counter now recognizes one odd appearance of 'a'.

3. State Transition:

Example Walkthrough

Process the second character 'b': The state changes with st ^= 1 << (ord('b') - ord('a')), so st becomes</li>

Let's consider the string word = "aba". We will walk through the solution approach step by step.

4. Counting Wonderful Substrings: For st = 0b0000000001 after processing the first 'a':

0b000000010. Now we have both 'a' and 'b' with odd appearances (but not in the same substring).

■ ans += cnt[st] (the previous same state), so ans = 0+1 = 1 because an all-even state was seen before, and the current state is the wonderful substring "a".

ans += cnt[st] (the previous same state), so ans = 1+0 = 1 because there's yet no state with only 'b' with an odd

Flip each bit in st and add those counts: There are no previous 1-bit-flipped states, so no addition here.

 Flipping each bit of st (checking for 0b0000000001 and 0b0000000010), we find ans += cnt[0b0000000001] = 1, hence ans = 2. This represents the wonderful substring "b".

and "aba".

count.

Update st using st ^= 1 << (ord('a') - ord('a')), st is now 0b0000000010 again.</li>

After the first 'a', cnt [0b0000000001] = 1 as we've seen the state of 'a' once.

# Toggle the bit for the current character in the mask state

After 'b', cnt [0b00000000010] = 1 as we've seen the state of 'b' once.

Now, process the third character, another 'a':

one letter having an odd count within the substring.

def wonderfulSubstrings(self, word: str) -> int:

# Iterate over the characters in the word

current\_mask ^= 1 << (ord(char) - ord('a'))</pre>

wonderful\_count += mask\_count[current\_mask]

# exactly one character with an odd count

# Return the total count of wonderful substrings

# Increment the count for the current mask state

Considering the state 0b0000000010 after processing 'b':

represents the substring "ab". 5. Updating the Counter: After each character is processed, we update the counter for the current state:

By flipping each bit in st and adding those counts, we find ans += cnt[0b0000000001] = 1; therefore, ans = 4. This

• ans += cnt[st] would result in ans = 2+1 = 3 because we have seen this state before, representing the substrings "b"

- After the second 'a', cnt[0b00000000010] = 2 since we've returned to this state. In the end, ans = 4. We have the wonderful substrings: "a", "b", "ab", "aba". Each of these substrings meets the criteria of at most
  - # Initialize a counter for the mask state, starting with the 0 state seen once mask\_count = Counter({0: 1}) # Initialize answer and mask state

# Add to the wonderful string count the number of times this mask state has been seen

# This covers the case where the substring has an even count of all characters

# Check all masks that differ by one bit, which correspond to having

# Toggle the i-th bit to check for a previous state that would

# complement the current state to make a wonderful substring

// The total number of wonderful substrings is now calculated in totalCount.

wonderful\_count += mask\_count[current\_mask ^ (1 << i)]</pre>

```
8
           wonderful_count = 0
9
            current_mask = 0
10
```

11
12
           // Add the count of the current state to the total count of wonderful substrings
```

# Time and Space Complexity

count[charState]++;

totalWonderfulSubstrings += count[charState];

for (let i = 0; i < 10; ++i) {

// Check every possible character state with one bit flipped

// Increment the count of the current character state

totalWonderfulSubstrings += count[charState ^ (1 << i)];

### Analyzing the code, the main part contributing to time complexity is the two nested loops: the outer loop iterating over each character of the string once, and the inner loop iterating 10 times for each character (since an alphabet in lowercase has 26 letters).

**Time Complexity:** 

13

14

15

16

17

18

19

20

21

22

23

24 // Return the total number of wonderful substrings 25 return totalWonderfulSubstrings; 26 } 27

 The inner loop runs up to 10 times for each iteration of the outer loop, irrespective of the input string. Thus, the overall time complexity can be computed as O(10n) or O(n) when we ignore the constant factor.

• The outer loop runs n times where n is the length of the input string word.

The operations within the loops (bitwise XOR, dictionary access/update) are constant time.

Hence, the time complexity of the code is: 0(n). **Space Complexity:** 

For space complexity, the code maintains a counter cnt dictionary that at most contains the number of different states that a bitset of size 10 (size corresponding to the first 10 alphabets) can have, plus 1 for the initial (0:1) state. The st variable holds the current state and changes in-place.

The states are bitsets that correspond to the parity (even or odd count) of each letter, and there can be 2^10 such states. So, the space complexity is determined by the number of different states that can be held in counter cnt, which gives us 2^10.

Therefore, the space complexity of the code is: 0(2^10) or 0(1) because 2^10 is a constant.
