

Problem Description

Sorting

In this problem, we are working with a candy shop that has a particular discount scheme: for every two candies purchased, a third candy is given for free. The caveat is that the cost of the free candy can't exceed the cost of the least expensive candy bought among the two. We need to find out how much the customer will have to pay in total to buy all the candies available in the shop considering this discount.

The given data is an integer array cost which represents the price of each candy. The array is 0-indexed, meaning that the first element is at index 0, the second at index 1, and so on. Our task is to calculate the minimum total cost required to buy all candies while making the most out of the given discount.

Intuition

candies for free when possible. Hence, the best strategy would be to sort the candies in descending order of their cost. That way, every time we pick two candies, they will be the most expensive ones available, and we can then choose one of the less expensive candies for free (following the rule that the free candy must be priced less than or equal to the cheaper of the two paid candies). After sorting, we can observe that in every three consecutive candies starting from the first (index 0), the third one (at index 2)

To minimize the total cost of buying all the candies while taking advantage of the discount, we should aim to get the more expensive

would be the free one if we adopt the purchasing pattern of buying in sets of three, so to speak. We continue this pattern throughout the array. Thus, by taking the sum of all candies' costs and subtracting the sum of every third candy post-sorting, we get the total minimum cost. This is exactly what the provided solution is doing: it sorts the list in reverse order, then sums up all elements, excluding every third element starting by the third (index 2, as the index is zero-based). That is the sum of all the costs of the free candies if we buy them in an optimal way. **Solution Approach**

The solution approach takes advantage of sorting and list slicing operations. Here's a step-by-step explanation of the implementation:

1. Sorting the list in reverse order: We use the sort method with the reverse=True parameter to rearrange the elements of the cost list in descending order. Sorting is a common algorithmic pattern when we need to rearrange data for optimization

purposes, such as minimizing or maximizing some value subject to constraints—in this case, the constraint is the "buy two, get one free" deal. cost.sort(reverse=True)

After this operation, the most expensive candies are at the beginning of the list, and the least expensive ones are at the end.

```
2. Calculating the total sum: The sum function calculates the total cost of the candies if there were no discounts. This serves as
```

total_cost = sum(cost)

our starting point for finding the minimum cost.

3. Identifying the free candies using slicing: The third step uses list slicing to identify all the candies that would be free. The slice operation cost [2::3] takes every third candy from the list, starting with the one at index 2 (zero-based index, which is the third

```
candy). This exploits a pattern that emerges from sorting the candies by cost: when they are sorted in descending order, each
set of three contains two paid candies followed by one free candy.
```

free_candies_cost = sum(cost[2::3]) 4. Subtracting the cost of free candies: By subtracting the sum of the free candies' costs from the total cost, we arrive at the minimum cost to buy all candies. This effectively applies the "buy two, get one free" discount across the entire list.

```
Putting it all together, the provided solution is a compact representation of these steps, combining the total calculation and the
```

subtraction of the free candies' costs into a single line:

minimum_cost = total_cost - free_candies_cost

return sum(cost) - sum(cost[2::3]) This approach is both elegant and efficient, as it avoids the need for explicit loops or additional data structures. The sorting

algorithm behind the sort method typically has O(n log n) complexity, where n is the number of candies, and the slicing operation

Example Walkthrough Let's suppose we have the following candy prices:

To understand the solution approach, let's walk through it step by step using this example:

from the total cost.

candies first.

1 cost = [1, 3, 2, 8, 5, 7]

1 cost.sort(reverse=True) // After sorting: cost = [8, 7, 5, 3, 2, 1]

1 minimum_cost = total_cost - free_candies_cost // minimum_cost = 26 - 6 = 20

has O(n) complexity. Thus, the overall complexity of the solution is dominated by the sorting step.

```
2. Calculating the total sum: Before applying the discount, calculate the total cost of all candies.
   1 total_cost = sum(cost) // total_cost = 8 + 7 + 5 + 3 + 2 + 1 = 26
```

1. Sorting the list in reverse order: We sort the cost list in descending order to prioritize the purchase of the most expensive

3. Identifying the free candies using slicing: According to the discount, for every two candies purchased, the third one is free, starting from the least expensive of the paid ones. To find the free candies applying the discount optimally, we take every third candy in the sorted list, beginning with the one at index 2.

4. Subtracting the cost of free candies: Finally, to get the minimum cost after the discount, subtract the total cost of free candies

1 free_candies_cost = sum(cost[2::3]) // The free candies are at indices 2 and 5, so free_candies_cost = 5 + 1 = 6

```
So, the minimum total cost to buy all candies while taking full advantage of the discounts is 20.
```

Python Solution

def minimumCost(self, costs: List[int]) -> int:

costs.sort(reverse=True)

min_cost -= sum(costs[2::3])

return min_cost

Return the calculated minimum cost

Sort the list of costs in descending order

Initialize the minimum cost to the sum of all costs

cost list. By following these steps, the provided solution effectively minimizes the total cost, ensuring that customers get the highest-priced candies possible for free, in compliance with the shop's discount policy.

Using our approach, we've paired the most expensive candies first ([8, 7], [5, 3]), then we get the least expensive candies as the free

items ([2] and [1]). The 2 and 1 correspond to the third items in each buying set, which are the free items according to our sorted

min_cost = sum(costs) # Subtract the cost of every third item starting from the third item # because it would be the free item as per the typical "buy two, get one free" offer. 10

Time Complexity:

operation.

17

if (i > 0) {

return totalCost; 18 20 Time and Space Complexity The given Python code aims to calculate the minimum cost of purchasing items given that every third item is free when items are purchased in descending order of cost. We will analyze the time and space complexity of the provided code.

// Return the total cost after applying the discount for every third flower

let totalCost = 0; // Initialize the total cost variable

for (let i = cost.length - 1; $i \ge 0$; i = 3) {

// Start iterating from the end of array towards the front

// We jump three steps at a time since every third flower is free

totalCost += cost[i]; // Add the cost of the current flower

// If there is another flower before the current one, add that cost too

because Python's Timsort algorithm is used for sorting, which has this time complexity. 2. The sum function iterates over the entire list, resulting in O(n) time complexity.

3. The slicing operation cost[2::3] generates a new list containing every third element from the list cost, leading to 0(n/3)

1. The sort function on the list cost has a time complexity of O(n log n) where n is the number of elements in the list cost. This is

- complexity, which simplifies to O(n).
- Combining these operations, the dominant term is the sorting operation. Thus, the total time complexity of the code is 0(n log n).

Space Complexity:

1. The sorting is done in-place, so there is no additional space required for this operation.

2. The sum function operates on the list without creating new structures, so it uses 0(1) space. 3. The slicing operation cost[2::3] creates a new list, which in the worst case, could be 0(n/3) space complexity. However, since

constants are dropped in Big O notation, it simplifies to O(n) space complexity. Therefore, the space complexity of the code is O(n), accounting for the space needed to store the new list generated by the slicing
