2131. Longest Palindrome by Concatenating Two Letter Words

Counting

Problem Description

Greedy Array

Hash Table

elements of words, the function should return 0.

String)

Medium

objective is to construct the longest possible palindrome by selecting and concatenating some elements from the given words array. We are allowed to use each element only once. A **palindrome** is defined as a sequence that reads the same both forwards and backwards. For example, "radar" and "level" are

In this problem, we have an array of strings called words. Each string is composed of exactly two lowercase English letters. Our

palindromes. We are required to return the length of the longest palindrome that can be created. If no palindromes can be formed using the

Intuition

To solve this problem, we need to find pairs of words that can contribute to the palindrome. There are two distinct scenarios to

consider:

symmetrically on either side of the palindrome. Palindrome pairs: Words that are palindromes in themselves (e.g., "aa", "bb"). They can be placed in the middle of the

Matching pairs: A pair of words where one is the reverse of the other (e.g., "ab" and "ba"). These can be placed

- palindrome or paired with themselves to be placed symmetrically.
- Our strategy is to count the frequency of each word and then iterate over our count dictionary to calculate the contribution of each word to the longest palindrome. For each word, we check:

middle). The count of these words can only contribute in even numbers for both halves of the palindrome. If there's an odd count, one instance can be placed in the middle.

If it's a palindrome pair (the word is the same when reversed), we can use it in pairs in the palindrome (e.g., "cc"..."cc" in the

If it's a matching pair (word and the reverse are different), we can use as many of these pairs as the minimum count of the

- An additional consideration is that we can only place at most one palindrome word in the very center of the palindrome. The primary steps of the solution include: • Counting each word's occurrence using a Counter structure for efficient lookup.
- Iterating over the unique words and calculating their potential contribution to the palindrome length. • If possible, adding an extra pair of letters if we have leftover palindrome pairs to maximize the palindrome length.

Based on this logic, the provided solution code computes the longest possible palindrome efficiently.

number of times that element appears.

times two v // 2 * 2 * 2.

having to explicitly build the palindrome.

"cc", "aa"].

• ab: 1

• ba: 1

code consists of a few key steps:

Solution Approach

word and its reversed pair.

The solution employs a Counter from Python's collections module to efficiently count the occurrences of each word in the words

For every unique word k and its count v in the counter:

Return ans as the length of the longest palindrome.

array. A Counter is essentially a dictionary where each key is an element from the input array and its corresponding value is the

 \circ If the word is a palindrome itself (the same forwards and backwards, i.e., k[0] == k[1]):

be placed at the center. If it's possible, add 2 to ans to account for the center element.

Initialize two accumulators: ans represents the length of the potential palindrome, and x represents the count of center elements that appear an odd number of times.

■ The half-count of such words v // 2 contributes to both halves of the palindrome. So the contribution would be double the half-count

■ If there's an odd count of a palindrome word (v & 1), we increment x, because it means we have an instance of this word that can

After iterating through all words, we check if x is greater than 0, which would mean that we have at least one word that can

We then iterate through the items in the Counter to determine how each word can contribute to the length of the palindrome. The

potentially be placed in the center of the palindrome. ∘ If the word is not a palindrome and has a complementary word that is its reverse (k[::-1]) in the array: ■ The contribution of such pairs is limited by the lesser count of the pair, hence we use min(v, cnt[k[::-1]]) * 2.

- In summary, by using a counter to track word frequencies and understanding the two types of pairs (matching and palindrome
- **Example Walkthrough**

Let's consider a small example to illustrate the solution approach using an array of strings words = ["ab", "ba", "aa", "cc",

pairs), we can efficiently calculate the maximum possible palindrome length. The solution is quite elegant as it minimizes the

amount of work necessary by directly computing the contribution each word can make to the final palindrome structure without

• aa: 2 • cc: 2

palindrome length ("ab" + "ba" or "ba" + "ab" on either side).

palindrome, adding 4 to the length ("aa" + "aa" on either side).

length of the longest palindrome that can be created.

def longestPalindrome(self, words: List[str]) -> int:

length_of_palindrome = central_letter_pair_count = 0

central_letter_pair_count += count % 2

length_of_palindrome += (count // 2) * 4

Check if the word is a pair of identical letters, like "aa"

length_of_palindrome += $min(count, word_count[word[::-1]]) * 2$

// Loop through the array of words to populate the map with word counts

wordCount.put(word, wordCount.getOrDefault(word, 0) + 1);

Counter.items() contains pairs of (word, count)

for word, count in word_count.items():

Create a count of all words

if word[0] == word[1]:

word_count = Counter(words)

Solution Implementation

else:

Python

Java

C++

public:

class Solution {

class Solution {

Next, we iterate over these counts and calculate how they contribute to the potential palindrome:

Therefore, the length of the longest palindrome that can be created from the given words array is 10.

Following the solution approach, we first use a Counter to count occurrences:

• The word "cc" is also a palindrome and has a count of 2. It contributes another 4 to the length like "aa" ("cc" + "cc" on either side). Since both "aa" and "cc" have even counts, there's no additional contribution to the center, so we have x = 0.

Adding together the contributions we get 2 (from "ab" and "ba") + 4 (from "aa") + 4 (from "cc") equals 10, which is the

Lastly, since there is no extra odd-count palindrome word to place in the center (x is 0), we don't add anything more to ans.

• The word "ab" has a count of 1. By checking its reverse, we find "ba" also has a count of 1. They can be used as a pair to contribute 2 to the

• The word "aa" is a palindrome itself and has a count of 2. This means it can contribute twice its half-count (which is 1) to both halves of the

from collections import Counter class Solution:

Count of such word pairs that can be used as the central part of the palindrome

For other pairs, add the minimum count of the pair and its reverse pair to the length

Add the count (rounded down to the nearest even number) times 2 to the length

If there are pairs of identical letters, we could place exactly one in the center of the palindrome length_of_palindrome += 2 if central_letter_pair_count else 0 return length_of_palindrome

class Solution:

Time Complexity

// After pairing, remove the entries so they are not re-counted

words in the input list, since it has to count the occurrences of each unique word. Iterating over the items in the counter. In the worst case, each word is unique, so this operation could iterate up to n times.

Therefore, the time complexity of the loop is also O(n).

Time and Space Complexity

The time complexity of the code is determined by a few factors:

For each word, we may check for its reverse in the counter. This is a constant time operation 0(1) given the nature of hashmaps (dict in Python).

Constructing the Counter object from the words list. This operation has a time complexity of O(n), where n is the number of

that would increase the order of complexity beyond linear. **Space Complexity**

The Counter object stores elements as keys and their counts as values. In the worst case, every word in words is unique,

The space complexity of the code is primarily affected by the storage requirements of the Counter object:

Adding the contributions from these operations, the overall time complexity is O(n). There is no nested iteration or operations

which means the Counter will store n keys and values. Hence, space complexity for the Counter is O(n). The integer variables ans and x use a constant amount of space, 0(1).

So, the overall space complexity of the function is O(n) due to the space taken by the Counter object. All other variables only contribute a constant space overhead which does not depend on the input size.

Therefore, the final space complexity is O(n).
