312. Burst Balloons

Dynamic Programming

all other balloons, we treat them as 1.

Problem Description

<u>Array</u>

Hard

from 0 to n - 1 and the numbers painted on them are given in an array called nums. Your task is to "burst" all of these balloons in such a way that allows you to collect the maximum number of coins possible.

The main rule to remember is that when you burst a balloon at index i, you collect a number of coins equal to the product of the

You are presented with a hypothetical situation involving n balloons, each painted with a number. These balloons are indexed

numbers on three balloons: the one at i, the one immediately before it (i - 1), and the one immediately after it (i + 1). If there is no balloon at i - 1 or i + 1 (which would be the case if i is at the start or end of the array), then you pretend there is a balloon with the number 1 painted on it.

The challenge is to find the sequence of bursting balloons that yields the highest total number of coins.

Intuition

To arrive at a solution for this problem, consider that the last balloon you burst would allow you to collect nums[0] * nums[1] * nums[n-1] coins, where i is the index of this last balloon. Since nums[0] and nums[n-1] would be out of bounds after bursting

This suggests a <u>dynamic programming</u> approach where we consider smaller subproblems and build up to the full solution. The intuition behind the provided solution is to transform the problem into considering the maximum coins that can be collected by bursting the balloons within a subinterval of the original array.

By iteratively expanding these intervals and calculating the maximum number of coins that can be collected when bursting the last balloon in these subintervals, we can use previously solved smaller intervals to help calculate larger intervals. This concept is similar to matrix chain multiplication, where optimal solutions to smaller subproblems can be used to construct the final solution.

The idea is to iteratively consider all possible subintervals and all possible last balloons to burst within each subinterval. By doing so, we use the <u>dynamic programming</u> (DP) array dp to store the maximum coins obtained for each subinterval, so that we do not have to re-calculate the coins for those intervals again. The process starts from the smallest intervals and works its way up to the interval covering the entire range.

In the implementation, the dp array is first initialized to store zero values. Then, for each subinterval length 1, starting at 2 and

going up to n, we calculate the maximum coins for starting subintervals at index i and ending at j, using all possible last

balloons k to find the best option. The final answer is then taken from the dp entry that covers the entire range, excluding the

artificial balloons at both ends (that only serve the purpose of simplifying boundary conditions).

Solution Approach

The solution approach involves dynamic programming, which is a method for solving complex problems by breaking them down

into simpler subproblems. The solution uses a 2D array, often referred to as a "DP table", to store the maximum number of coins that can be collected by bursting balloons within a specific subinterval of the array.

Let's delve into how the solution is implemented:

1. We first add a 1 at the beginning and the end of the nums array. This step simplifies our calculations for cases when we burst

the first or the last balloon in the original array. 2. We define n as the length of this new array, now including the two additional balloons with a 1 painted on them.

the bounds of the array.

4. We iterate through all possible lengths of subintervals 1, starting from 2. We choose 2 because a subinterval must contain at least one balloon to burst (situated between the two 1s we added).

We initialize a 2D array called dp with dimensions n by n, setting all values to 0. dp[i][j] will store the maximum coins that

For each subinterval length (1), we find the start (i) and end (j) of the subinterval. We restrict our subinterval to be within

coins collected from bursting balloon k last, which is nums[i] * nums[k] * nums[j], and add to it the coins collected from

6. For each subinterval from i to j, we consider each balloon k as the last balloon to burst in this subinterval. We calculate the

can be collected by bursting all balloons between index i and j.

the subintervals [i, k] and [k, j] which we have already calculated and stored in our dp table previously.

7. We update dp[i][j] with the maximum number of coins found for bursting all balloons between i and j.

The nested loops in the code iterate over subintervals and the potential last balloons that could be burst in that interval. The

Finally, the result is the value in dp[0] [n-1], where n-1 is the index after the last artificial 1.

This solution effectively builds the solution from smaller intervals to larger ones and uses previously computed results for efficiency, avoiding redundant calculations.

Let's consider an example with the following balloon numbers: nums = [3, 1, 5, 8]. Following the given solution approach:

1. We first add 1 at the beginning and the end to get [1, 3, 1, 5, 8, 1] to account for the boundaries.

 \circ Similarly, for [2,4], bursting 1 would give 3 * 1 * 5 = 15 coins, and so on for the other subintervals.

We initialize a 6x6 DP table with zeros. This table will help us remember the best solutions for subproblems.

innermost loop picks the best choice for the last balloon to maximize the coins collected.

We consider subinterval lengths 1 starting from 2, because a subinterval should have at least one balloon.
 For 1 = 2, we have subintervals [1,3], [2,4], [3,5], and [4,6]:

 \circ For subinterval [1,3], the only balloon to burst is 3 (as 1 and 1 are our added boundaries), and it gives 1 * 3 * 1 = 3 coins.

o Take [1,2,4], if we decide to burst balloon 2 last, we get 1*1*5+dp[1][2]+dp[2][4]=5+3+15=23 coins. For [2,3,5], the last burst 3 gives 3*5*1+dp[2][3]+dp[3][5] coins, and so on.

5, 8, 1].

l=2:

subinterval is the entire array.

Example Walkthrough

The length n of the new array is 6.

Our DP table is updated for these subintervals.

choose the maximum among them to update our DP table.

Walkthrough example with detailed subinterval analysis:

With l = 3, we have subintervals [1,2,4], [2,3,5], and [3,4,6]:

 \circ Subinterval [1,3] (burst 3): dp[1][3] = 1 * 3 * 1 + dp[1][2] + dp[3][3] = 3

 \circ Subinterval [2,4] (burst 1): dp[2][4] = 3 * 1 * 5 + dp[2][2] + dp[4][4] = 15

We update our DP table accordingly.

This process is continued, expanding the size of subintervals until 1 = n - 1, where n is the length of our new array, and our

The result would then be in dp[0][n-1] which in this case will store the maximum number of coins we can collect from [1, 3, 1,

For each subinterval at each 1, we consider all possible balloons that could be burst last, calculate the coins we can collect, and

bursting 3 last) = max(1*1*5+dp[1][2]+dp[3][4], 1*3*5+dp[1][3]+dp[4][4]) = max(23, 15+0+0) = 23

Calculate the maximum coins that can be obtained by bursting the balloons wisely.

Add a balloon with value 1 to each end of the list to simplify calculations

dp[i][j], # Current max coins for range (i, j)

// Copy the original nums array into the extendedNums array, starting at index 1.

The maximum coins obtained will be in the top right corner of the dp table

// Method to calculate the maximum coins after bursting all the balloons.

// Initialize an extended array that includes 1s at both ends.

System.arraycopy(nums, 0, extendedNums, 1, nums.length);

for (int i = 0; i + windowLength < n; ++i) {

for (int k = i + 1; k < j; ++k) {

int j = i + windowLength;

return dp[0][n - 1];

Time Complexity

return dp[0][-1]

The given code implements the dynamic programming approach to solve the burst balloons problem. The time complexity of the code is dependent on the nested loops used in the algorithm.

There is an outer loop that iterates through all possible lengths of the subarrays (denoted by 1), which goes from 2 to n. So,

- There is an outer loop that iterates through all possible lengths of the subarrays (denoted by 1), which goes from 2 to n. So, it iterates n 2 times.
- For every possible length, there is a nested loop iterating over the start indices of the subarrays (denoted by i), and this runs for n 1 iterations for each 1.
 Inside the second loop, there is an innermost loop that iterates through all possible k positions where the balloon can be
- burst, between the start and end of the subarrays (from i + 1 to j 1 where j = i + 1).

 The combination of these nested loops looks something like a cubic number of operations, giving us a time complexity of $O(n^3)$,

Space Complexity The space complexity is ma
