1502. Can Make Arithmetic Progression From Sequence

Problem Description

to form an arithmetic progression. An arithmetic progression is a sequence of numbers where the difference between any two consecutive numbers is always the same. For example, in the sequence [1, 3, 5, 7], the difference between consecutive elements is 2, which is consistent throughout the sequence, so it is an arithmetic progression. The goal is to return true if the given array can be rearranged to form such a sequence, or false otherwise.

The problem gives us an array of numbers named arr and asks us to determine whether we can rearrange the array's elements

Intuition

array is sorted, we calculate the common difference, which should be the difference between the first two elements (since the sorted array should now represent an arithmetic progression if one is possible). After calculating this common difference, we iterate through the array to check if every consecutive pair of elements has this same difference. If at any point we find a pair of elements that do not have the common difference, we can conclude that it is not

The intuition behind the solution is to first sort the array. Sorting the array is a key step because if an arithmetic progression

exists, it must be the case that when sorted, the difference between each pair of consecutive elements is consistent. Once the

possible to form an arithmetic progression and should return false. If we successfully iterate through the entire array without finding discrepancies, then the array can indeed form an arithmetic progression and we return true. The pairwise function utilized in the solution is a Python utility that allows us to iterate through the array in element pairs which simplifies the process of checking the difference between consecutive elements. With all, we check if all pairs have the same

difference d, and hence it satisfies the condition of an arithmetic progression. **Solution Approach**

The solution approach leverages a sorting algorithm and a simple iteration pattern to verify the arithmetic progression. Here's a

step-by-step breakdown of the implementation applied in the provided Python code:

sorted array.

Sorting the Array: The first line in the function sorts the array in-place using arr.sort(), which is a built-in Python method that sorts the list ascendingly by default. The sorted array is necessary to easily compare the difference between consecutive elements.

Finding the Common Difference: The variable d is computed as arr[1] - arr[0] i.e., the difference between the first two

elements of the sorted array. This difference d is what we expect between every pair of consecutive elements in an

The pairwise function is from Python's itertools module (potentially, the grouper pattern could also be used), which is used

here to iterate over the array elements in pairs. Each pair of elements (a, b) consists of consecutive elements from the

If any pair does not satisfy this, all will immediately return False, indicating that the progression cannot be formed.

- arithmetic progression. Verifying the Arithmetic Progression: The last step is to verify if each consecutive pair of elements in the sorted array has the same difference d. This is done using the expression all(b - a == d for a, b in pairwise(arr)).
- The all function ensures that every element of the provided iterator evaluates to True. It processes the generator expression, which for each pair of elements checks if the difference b - a is equal to d.
- Otherwise, it will return True, confirming that the array is indeed an arithmetic progression. The elegance of this approach lies in its simplicity and the efficient use of Python's standard libraries to achieve the desired

outcome with very few lines of code. Since sorting is the most computationally expensive part of the algorithm, the overall time

complexity is 0(n log n) where n is the number of elements in the array due to the sorting operation. The verification process

has a time complexity of O(n) since it iterates through the sorted elements once. Therefore, the total time complexity remains

0(n log n). **Example Walkthrough** Let's take an example to illustrate the solution approach. Consider the array arr = [9, 5, 1, 3, 7]. Our goal is to check whether we can rearrange this array into an arithmetic progression.

Sorting the Array: We first sort the array, which results in arr = [1, 3, 5, 7, 9]. Finding the Common Difference: We calculate the common difference d as the difference between the first two elements,

to d.

return True.

class Solution:

Java

class Solution {

class Solution {

public:

arr.sort()

Following the solution approach:

which is d = arr[1] - arr[0] = 3 - 1 = 2. Verifying the Arithmetic Progression: We then check if the difference between every consecutive pair of elements is equal

Since all pairs have the same difference, which is equal to d, the function all(b - a == d for a, b in pairwise(arr)) would

conclusion that arr can be rearranged to form an arithmetic progression, and thus, the final answer is true.

 \circ The difference between the second and the third elements (3 and 5) is 5 - 3 = 2, which is equal to d.

 \circ The difference between the third and the fourth elements (5 and 7) is 7 - 5 = 2, which is again equal to d.

 \circ The difference between the fourth and the fifth elements (7 and 9) is 9 - 7 = 2, which is also equal to d.

Therefore, based on the solution approach, we can conclude that it is indeed possible to rearrange the array [9, 5, 1, 3, 7] to form an arithmetic progression [1, 3, 5, 7, 9].

The consistent common difference and the successful run of the all function on pairwise compared elements support the

Python from typing import List

Calculate the common difference 'd' between the first two elements common_difference = arr[1] - arr[0]

```
return False
# If all differences are equal, return True (it is an arithmetic progression)
return True
```

Solution Implementation

elements has the same difference 'd'

if arr[i + 1] - arr[i] != common_difference:

O(n-1) or simply O(n) since it's walking through the array only once.

the default sort function uses an algorithm called Timsort, which has a time complexity of O(n log n), where n is the length of the array. The subsequent operation consists of iterating through the sorted array to check if every pair of successive elements has the same difference, d. This check uses a generator expression with the all() function combined with pairwise iteration, which is

The time complexity of the canMakeArithmeticProgression function is determined primarily by the sorting operation. In Python,

Thus, the dominating factor here is the sorting, and the overall time complexity of the function is $0(n \log n)$. **Space Complexity**

Python's Timsort requires 0(n) space in the worst case. The pairwise iteration does create pairs for every two adjacent elements in the array, but since this is done by the generator

expression, it doesn't create an additional list in memory, it simply iterates through the existing sorted array yielding one element at a time.

Hence, the space complexity of the function, which is mostly governed by the sorting operation's space requirement, is O(n).

For space complexity, the sort operation can be done in-place, but certain implementations may require additional space.
