970. Powerful Integers

Medium Hash Table **Math**

Problem Description

raised to the power of i and y raised to the power of j, where i and j are non-negative integers (i.e., i >= 0 and j >= 0). The twist here is that we are only interested in those sums that do not exceed a given limit, bound. The result should be a list of these powerful integers, and each should only appear once, regardless of the order they're presented in.

Given three integers x, y, and bound, the task is to find all unique powerful integers. A powerful integer is defined as the sum of x

Intuition

a maximum value. To solve this efficiently, we think of what happens when we increment these exponents: as i or j increase, the value of x^i or y^j grows exponentially. So, even if x and y are as small as 2, by the time they are raised to the 20th power, they are already greater than 10^6 (2^2) > 10^6), which exceeds the typical constraints of bound. Based on this observation, we can intelligently limit our search for potential values of i and j. This way we avoid calculating large powers that would exceed the bound. More specifically, we need to ensure the sums x^i + y^j are within the bound, and we only

The key to solving this problem is recognizing that we only need a reasonable range of powers for x and y since they're bound by

need to look for values of i and j that meet this requirement. When either x or y is 1, it doesn't make sense to keep increasing the power, because 1 raised to any power is still 1. This means

that if x or y is 1, we loop through its power only once, rather than continuing to increase it, which would just give us the same result. If neither x nor y is 1, we proceed with the nested loop, ensuring each time that the sum x^i + y^j does not exceed bound.

The solution uses a set to collect the sums to automatically handle duplicates and ensure that each powerful integer is only counted once. After looping through all potential combinations, we convert the set to a list to provide the answer that matches the problem's expected return type.

Solution Approach The implementation strategy for finding all powerful integers within the specified bound takes advantage of some basic

algorithmic principles and the properties of mathematical exponents. Let's go step by step through what the provided Python

solution does: Set Data Structure: The solution uses a Python set, called ans, as the primary data structure to store the powerful integers.

The set is chosen because it can automatically manage duplicates, which means any sum computed more than once will only be stored once in the set. Loop Bounds for Efficiency: To keep the algorithm efficient, we determine the powers of x and y within a restricted loop

- bound, as the Reference Solution Approach suggests. If x and y are both greater than 1, i and j will never need to exceed 20 because x^i or y^j would be greater than 10^6. Hence, we can cap our loop to not exceed the bound. **Nested While Loop and Exponentiation**: A double-nested while loop is employed to go through all the viable powers of x and
- Breaking Conditions: Within each loop iteration, we check that the current powers' sum a + b is less than or equal to bound. If it isn't, we don't need to explore higher powers of y for the current x exponent and break out of the inner loop. Similarly, if x is

y. The outer loop is for the variable a representing x^i , and the inner loop for b representing y^j .

Early Termination: If we find that x or y is 1, we can optimize further by breaking out of the respective loop immediately after the first iteration. This is because any exponent of 1 is still 1, and so further iterations would not provide any new sums.

1, increasing i won't change the value of a, so we break out of the outer loop. The same logic applies for y.

Adding to the Set: For each valid pair of powers found within the loops, the sum a + b is added to the set ans.

within the bound. The set is cast to a list, and then the list is returned as the final result. The above solution ensures we consider all possible sums within the constraint efficiently without redundant calculations or

Final Result: Once all potential a and b values have been tried, the set ans contains all the unique powerful integers that fall

Example Walkthrough Let's assume our input values are x = 2, y = 3, and bound = 10. Our goal is to find all unique powerful integers that can be

Step-by-step Calculation: Initial Set: We start with an empty set ans to hold the values of all unique powerful integers.

Identify Loop Bounds: We assume the cutoff for i and j is 2 because if x or y is raised to the power of 3, the result is $2^3 = 8$

represented as 2ⁱ + 3^j where i and j are non-negative integers, and the result does not exceed the bound of 10.

Start with i = 0; calculate $a = 2^i = 2^0 = 1$.

Nested Loops:

concerns about duplicates.

Check if a + b = 1 + 1 = 2 is less than or equal to 10, it is, so add 2 to our set ans. Stay in the inner loop with j = 1; calculate $b = 3^j = 3^1 = 3$.

Check if a + b = 1 + 9 = 10 is less than or equal to 10, it is, so add 10 to our set ans.

and $3^3 = 27$, and any sum involving 27 would exceed our bound of 10.

Now enter the inner loop with j = 0; calculate $b = 3^j = 3^0 = 1$.

j = 3 would exceed our cutoff, so we do not increment j further.

Increment j to 2; calculate $b = 3^j = 3^2 = 9$.

- Check if a + b = 1 + 3 = 4 is less than or equal to 10, it is, so add 4 to our set ans.
- \circ With i = 2; calculate $a = 2^i = 2^2 = 4$. • Repeat the inner loop with j = 0 and j = 1, adding 4 + 1 and 4 + 3 to our set ans, but the sum with j = 2 would exceed the bound, so it's

not added.

Python

Next Outer Loop Iteration:

Last Outer Loop Iteration:

 \circ With i = 1; calculate $a = 2^i = 2^1 = 2$.

Result Construction: The values in our set ans are the powerful integers: {2, 4, 5, 10}.

formed without exceeding the bound.

integers does not matter, and the uniqueness is guaranteed by the set data structure. **Solution Implementation**

Loop through increasing powers of y and add to base_x while the sum is within the bound

Loop through increasing powers of x while it's less than or equal to the bound

If y is 1, it will always be 1, so break to avoid infinite loop

If x is 1, it will always be 1, so break to avoid infinite loop

Multiply base_y by y to get the next power of y

After converting this set to a list, the final answer we return is [2, 4, 5, 10]. It's important to note that the order of these

Repeat the inner loop with j = 0 through 2, adding 2 + 1, 2 + 3, and 2 + 9 to our set ans if not exceeding the bound.

class Solution: def powerfulIntegers(self, x: int, y: int, bound: int) -> List[int]: # Initialize an empty set to hold the unique powerful integers

Loop Completion: Once all combinations of i and j have been tested, we find that no further valid powerful integers can be

while base_x + base_y <= bound:</pre> # Add the sum of the powers to the set to ensure uniqueness powerful_ints.add(base_x + base_y)

 $base_x = 1$

while base_x <= bound:</pre>

base_y *= y

if y == 1:

break

 $base_y = 1$

Time and Space Complexity The time complexity of the code is determined by the nested while loops that iterate over the variables a and b. Since both a and b are exponentially increased by multiplying by x and y, the number of iterations is proportional to the logarithm of the bound. More specifically, the outer while loop runs until a exceeds bound, which happens after $0(\log_x(bound))$ iterations if x > 1, and only once if x == 1. Similarly, for each value of a, the inner while loop runs until b exceeds bound - a, which happens after $0(\log_y(bound))$ iterations if y > 1, and only once if y == 1. The overall time complexity is, therefore, $0(\log_x(bound))$ $log_y(bound)$), which can also be expressed as $O((log_bound)^2)$ assuming x and y are greater than 1. If either x or y is 1, the complexity would drop to $O(\log bound)$ or O(1) for x and y being 1 respectively.

The space complexity is determined by the size of the set ans, which contains all the different sums of a and b that do not exceed bound. In the worst case, every pair (a, b) is unique before reaching the bound. The size of the set would then be proportional to the number of pairs we can form, which is $0(\log_x(bound) * \log_y(bound))$, hence making the space complexity $0((\log_x(bound)))$ bound)^2) for x and y greater than 1.

- In summary:
- Time Complexity: 0((log_bound)^2) when x > 1 and y > 1; 0(log_bound) when either x or y is 1; 0(1) when both x and y are 1. • Space Complexity: 0((log_bound)^2) for x and y greater than 1; otherwise, it will be less depending on the number of unique sums obtainable when either x or y equals 1.
