

Problem Description

In this problem, we are given an array of integers, where the array is 0-indexed, meaning indexing starts from 0. A subarray is defined as a contiguous non-empty sequence of elements within the array. The alternating subarray sum is a special kind of sum where we alternately add and subtract the elements of the subarray starting with addition. For example, if the subarray starts at index i and ends at index j, then the alternating sum would be calculated as nums[i] - nums[i+1] + nums[i+2] - ... +/- nums[j].

The objective is to find the maximum alternating subarray sum that can be obtained from any subarray within the given integer array nums.

To solve this problem, we need to take into consideration that the sum we are looking to maximize can switch from positive to

Intuition

negative numbers and vice versa because of the alternating addition and subtraction. A brute force approach would involve checking all possible subarrays, but this would not be efficient, especially for large arrays. Consequently, we turn to dynamic programming (DP) to optimize our process. The solution builds on the concept that the maximum

alternating sum ending at any element in the array (which is either added or subtracted) can be based on the maximum sum we've computed up to the previous element. We keep two accumulators, f and g, at each step of our iteration through the array. f represents the maximum alternating subarray

sum where the last element is added, and g is where the last element is subtracted. At each iteration, f can either be the previous g (plus the current element, if g was at least 0, indicating a previous alternating subarray contribution), or it can directly be the current element if including the previous sequence doesn't yield a larger sum. Concurrently, g becomes the previous f minus the current element. By maintaining and updating these two values at each step, we can ensure that the maximum alternating subarray sum can be

is the highest value achieved by either f or g during the iteration. Solution Approach

computed in a single pass, thus significantly reducing the time complexity from what a brute force method would entail. The answer

The solution employs a dynamic programming (DP) approach to solve the problem efficiently. The key insight of the DP approach is to define two states that represent the maximum alternating subarray sum at each position i in the array nums.

 f is defined to be the maximum alternating subarray sum ending with nums [1] being added. g is defined to be the maximum alternating subarray sum ending with nums [1] being subtracted.

- The solution initiates f and g with the value -inf to represent that initially, there's no subarray, hence the alternating sum is the
- smallest possible (negative infinity). As the array is traversed, f and g will be updated for each element.

Here's how f and g get updated for every element in nums: 1. f gets updated to the maximum of g + nums[i] or 0 plus nums[i]. In essence, this step decides whether to extend the

alternating subarray by adding the current number to the previously best alternating sum ending with a subtracted number, or to start fresh with the current number if no profitable alternating subarray exists before it (in which case g would be non-positive).

- 2. g gets updated to f nums [i] from before the update in step 1. This step effectively chooses to continue the alternating subarray by transitioning from addition to subtraction at this element. The overall answer, ans, will be the maximum of all such f and g values computed. This ensures that at the end of the iteration
- The mathematical formulas involved in updating f and g are as follows:

through all elements in nums, and will store the maximum alternating subarray sum of any potential subarray within nums.

f = max(g + nums[i], nums[i]) which equates to f = max(g, 0) + nums[i] since adding a negative g would be less beneficial than just starting fresh from nums [i].

Lastly, for each iteration, and is updated to the larger of itself, f or g. At the end of the loop, and will hold the final maximum alternating subarray sum, which the function returns.

Example Walkthrough Let's consider a small example to illustrate the solution approach with the array nums = [3, -1, 4, -3, 5].

Initially, we set f and g to negative infinity, representing no sum because we haven't started the process, and ans to negative infinity

g = f_previous - nums[i]

to track the maximum sum we discover.

with the maximum of ans, f and g, so ans = max(-inf, 3, -inf) = 3. No need to update g yet since we only have one element.

Starting with the first element (3), we update f since no previous sum exists. So, f becomes max(-inf, 0) + 3 = 3. We update ans

• g gets updated to the previous value of f minus the current element, so g = 3 - (-1) = 4. • f gets updated to the max of current g plus the element or just the element, so f = max(0 + -1, 4 + -1) = 3.

Moving on to the third element (4):

For the second element (-1), we now have a subarray to consider:

- g gets updated to f from the previous step minus the current element, so g = 3 − 4 = −1. • f is updated to be $\max(0 + 4, -1 + 4) = 4$ because the previous g was negative.
- ans is updated to max(4, -1, 4) = 4.

• ans now becomes max(3, 4, 3) = 4.

• g gets updated to f from the previous step minus the current element, so g = 4 - (-3) = 7.

Finally, for the last element (5):

For the fourth element (-3):

- f is not any larger when updating with the current g, so f remains $\max(0 + -3, 7 + -3) = 4$. • ans is updated to max(4, 7, 4) = 7.
- g gets updated, g = 4 5 = -1.

sum_even_idx = float('-inf') # Sum at an even index of the alternated subarray

sum_even_idx, sum_odd_idx = max(sum_odd_idx, 0) + num, sum_even_idx - num

Update the maximum sum found so far by comparing with the new sums

// Calculate temporary sum for the subarray ending at an even position.

long tempEvenSum = Math.max(oddPositionSum, 0) + num;

// Update the sum for the subarray ending at an odd position.

sum_odd_idx = float('-inf') # Sum at an odd index of the alternated subarray

Update the sum at an even index. It is the greater of

or starting a new subarray from the current number.

• ans is updated to max(7, -1, 5) = 7. After completing the iteration, and holds the value of 7, which is the maximum alternating subarray sum of any subarray within nums.

Python Solution

for num in nums:

18
Time and Space Complexity
The given Python code defines a method maximumAlternatingSubarraySum which calculates the maximum sum of any non-empty
```

Time Complexity To understand the time complexity, let's go through the code:

1. The function iterates through the array nums once using a for loop (line 4). 2. Within each iteration of the for loop, it performs a constant number of operations: updating f, g, and ans (line 5). 3. No additional loops or recursive calls are present.

maxSum = max({maxSum, sumEven, sumOdd});

return maxSum; // Return the maximum alternating subarray sum

subarray from nums, where the sign of the elements in the subarray alternates.

- Since the number of operations within the loop does not depend on the size of the array, and the loop runs n times where n is the number of elements in nums, the time complexity is linear with respect to the length of the array, which we represent as O(n).
- **Space Complexity** Now, let's examine the space complexity:
- 1. The solution uses a fixed number of extra variables ans, f, and g (line 3), independent of the input size. 2. No additional data structures dependent on the input size are utilized.

Taking the above points into consideration, the space complexity of the algorithm is constant, denoted as 0(1) since the additional space used does not scale with the size of the input.

3. No recursive calls are made that would add to the call stack and therefore increase space complexity.
