1967. Number of Strings That Appear as Substrings in Word

Problem Description

number of strings from the patterns array that are also substrings of the word. A substring is defined as a sequence of characters that appear in unbroken succession within another string. For example, "cat" is a substring of "concatenate".

To solve this problem, we must check each pattern in the patterns array and determine whether it can be found within the word.

The problem gives us an array of strings called patterns and a single string called word. Our task is to count and return the

Every time we find a pattern that is a substring of word, we increment our count by one. Once we have checked all the patterns, we return the total count.

The solution leverages a simple yet efficient approach:

Intuition

Check if the current string pattern is a substring in word.

- Count the number of occurrences where a pattern is a substring of word.
- Count the number of occurrences where a patter

Iterate through each string in the patterns array.

In Python, this solution is very concise due to the language's concise syntax for string containment (in keyword) and list comprehensions (or generator expressions). The expression p in word returns True if pattern p is a substring of word and

Here's a step-by-step walkthrough of the implementation:

whether p is a substring of word, and yields True or False accordingly.

expression is the key part of this solution:

A generator expression is used to iterate through all patterns, yielding a True (equivalent to 1) or False (equivalent to 0) for each check. The sum function is then used to add up these values, resulting in the total count of patterns that are substrings of word.

Solution Approach

The solution to this problem is a straightforward application of string manipulation and searching. No complex algorithms or

additional data structures are necessary. This is because Python's inherent abilities to handle string operations make it an ideal

language for such tasks.

False otherwise.

The solution defines a class Solution with a method numOfStrings that takes in two arguments: a list of strings patterns and a single string word.
 The method numOfStrings returns the result of a sum function which is applied to a generator expression. The generator

sum(p in word for p in patterns)

```
This line uses the in keyword, which in Python, checks for the existence of a substring within another string.

The generator expression (p in word for p in patterns) goes through each pattern p in the patterns list, checks
```

a substring in word.

The sum function then adds up these 1s and 0s. The result is the total number of times a pattern from patterns is found as

The complexity of the solution is O(n * m) where n is the number of patterns and m is the length of the string word, assuming

Each True or False is implicitly converted to 1 or 0 as the sum function evaluates the expression.

- the in keyword takes O(m) in the worst case (when the pattern is similar to the end part of word and has to be checked for each character).
- No additional data structures are utilized, and the Python-specific in keyword optimizes the string searching, making the code concise and easy to understand.

 Example Walkthrough

Let's say we have a list of patterns ["a", "abc", "bc", "d"] and the word "abc". To determine how many strings from the

patterns array are substrings of the word, we proceed as follows:

1. We start with the pattern "a". Is "a" a substring of "abc"? Yes, it is. The string "abc" does contain the substring "a". So we

2. Next, we check the pattern "abc". Is "abc" a substring of "abc"? Yes, the whole word is a match. We increment our count again. Now the count is 2.

same.

class Solution:

word = "abc"

Using the solution approach:

patterns = ["a", "abc", "bc", "d"]

Create an instance of Solution

if pattern in word:

count_matches += 1

for (String pattern : patterns) {

if (word.contains(pattern)) {

can count that. Now our count is 1.

Then, we check "bc". Is "bc" a substring of "abc"? Yes, "bc" appears at the end of "abc" so it's a match. We update the count again. The count is now 3.

Finally, we check "d". Is "d" a substring of "abc"? No, "abc" does not contain the substring "d". The count remains the

- At the end of this process, we have found that 3 of our patterns are also substrings of the word "abc". Therefore, the method numOfStrings would return 3 for this example using the generator expression as described above.
- def numOfStrings(self, patterns, word):
 return sum(p in word for p in patterns)
 # Our example patterns and word

solution instance = Solution()
Call numOfStrings method and print the result
print(solution_instance.numOfStrings(patterns, word)) # Output: 3

```
Walkthrough.

Solution Implementation

Python

from typing import List

class Solution:
    def num of strings(self. patterns: List[str], word: str) -> int:
        # Initialize the count of matches
        count_matches = 0

# Iterate over each pattern in the list of patterns
for pattern in patterns:
```

This code snippet shows how to use the Solution class to solve our example. The output 3 matches our manual count from the

Return the total number of matches found
return count_matches
The class method num of strings() receives 'patterns', a list of strings, and 'word', a single string.

Check if the current pattern is a substring of the word

It counts how many strings in 'patterns' are substrings of the 'word' parameter.

// Check if the current pattern is contained within 'word'

count++; // Increment the count if the pattern is found

// Function to count the number of strings in 'patterns' that are substrings of 'word'

int count = 0; // Variable to keep track of the number of substrings found

If yes, increment the match count

public int numOfStrings(String[] patterns, String word) {

// Iterate through each pattern in the 'patterns' array

// Return the total count of patterns found within 'word'

#include <vector>

#include <string>

class Solution {

Java

class Solution {

return count;

```
public:
    // Function that counts the number of patterns found within a given word.
    int numOfStrings(vector<string>& patterns, string word) {
        int count = 0; // Initialize the count of found patterns to 0
        // Iterate over each pattern in the patterns vector
        for (auto& pattern : patterns) {
            // Check if the current pattern exists within the word
            if (word.find(pattern) != string::npos) {
                count++; // Increment the count if the pattern is found
        return count; // Return the total count of patterns found in the word
TypeScript
// Counts the number of strings in 'patterns' that are substrings of 'word'
function numOfStrings(patterns: string[], word: string): number {
    // Initialize a counter for the number of substrings found
    let count = 0;
    // Iterate through each pattern in the patterns array
```

def num of strings(self, patterns: List[str], word: str) -> int: # Initialize the count of matches count_matches = 0

class Solution:

return count;

from typing import List

```
# If ves, increment the match count
count_matches += 1

# Return the total number of matches found
return count_matches

# The class method num of strings() receives 'patterns', a list of strings, and 'word', a single string.

# It counts how many strings in 'patterns' are substrings of the 'word' parameter.

Time and Space Complexity

Time Complexity

The time complexity of the given function primarily depends on two factors: the number of strings in the patterns list and the length of the word string. For each pattern, the function checks whether that pattern exists within the word, which is an O(n) operation where n is the length of the word. Assuming the average length of the patterns is k, and there are m patterns in total,
```

operation where n is the length of the word. A the overall time complexity would be O(m * n).

for (const pattern of patterns) {

for pattern in patterns:

if pattern in word:

count++;

if (word.includes(pattern)) {

// Return the total count of substrings found

// Check if the current pattern is a substring of 'word'

Iterate over each pattern in the list of patterns

Check if the current pattern is a substring of the word

// Increment the count for each pattern found within 'word'

Therefore, if m is the number of patterns and n is the length of the word, the time complexity is:

0(m * n)

0(1)

Space Complexity

The space complexity of this function is O(1) because it uses only a constant amount of additional memory outside of the inputs.

The sum operation with a generator expression does not create a new list in memory; it simply iterates over the patterns and

accumulates the count. No additional data structures are used that would scale with the input size.

Hence, the space complexity is:
