2605. Form Smallest Number From Two Digit Arrays

array. We ensure to test both possible concatenations and choose the smaller one.

Problem Description

nums 2. The arrays contain unique digits, meaning each digit from 0 to 9 appears at most once in each array. We are looking to build the smallest number possible using only one digit from each array, without repeating any digit. To achieve the smallest number, we generally should start with the smallest digit from the two given arrays. However, if both arrays

The task here involves finding the smallest number that comprises at least one digit from each of the two given arrays, nums1 and

Leetcode Link

ensuring the number is as small as possible. If there are no common digits, we have to take the smallest digit from each array and combine them to form a two-digit number, carefully arranging them in an order that results in the smallest possible number. Intuition

straightforward; we just output this digit. However, if there isn't, we need to create a two-digit number using the smallest digit from

each array. Solution 1: Enumeration

The solution is intuitive once we understand the problem's requirements. If there is a common digit, our job becomes very

Solution 2: Hash Table or Array + Enumeration Using a hash table or an array allows us to keep track of which digits are present in each array more efficiently. We need a fixed-

common digit, we return it; if not, we proceed with concatenating the smallest digit from one array with the smallest from the other

Solution 3: Bit Operation This approach leverages the limited range of digits (1 to 9) and uses bit manipulation to effectively track which digits are present in each array. The main insight here is that each bit in a 10-bit binary number can represent the presence (1) or absence (0) of a corresponding digit. Using bit 'OR' operations, we can quickly build a bitmask for each array that reflects its content. We then perform a bit 'AND' operation to find any common digits. If we find none, we identify the position of the last 1 bit in each mask to find

the smallest digits from each array, concatenate these digits in both possible orders and return the smallest of the two values.

The solution implements the third approach, which leverages bit manipulation to efficiently determine the smallest number that

nums1 and nums2, respectively.

 Building Bitmasks: We iterate through each number x in both nums1 and nums2 separately and update the corresponding masks using an 'OR' operation (|= 1 << x). The 'OR' operation ensures that the bit at the position corresponding to the digit x is set to 1.

• Initializing Masks: We initialize two bitmask variables, mask1 and mask2, to zero. These will represent the presence of digits in

- found by the position of the last 1 in mask, which is calculated as (mask & -mask).bit_length() 1. • Extracting Smallest Non-Common Digits: If mask is zero, it means there are no common digits. We find the position of the last 1
- Forming the Smallest Number: Depending on whether a common digit exists, the smallest number is either the position of the last 1 in mask or the minimum of two numbers created by concatenating a and b in different orders (min(a * 10 + b, b * 10 + a)).
- time complexity is linear, 0(m + n), where m and n are the lengths of nums1 and nums2, because we only need single passes through each array to build the bitmasks.

 We start by initializing two bitmasks, mask1 and mask2, to zero (0). **Building Bitmasks:**

• For digit 4, the binary representation of 1 << 4 is 10000. Performing mask1 |= 10000 results in mask1 = 10000.

• For digit 3, the binary representation of 1 << 3 is 01000. Performing mask1 |= 01000 updates mask1 to 11000.

○ For digit 1, the binary representation of 1 << 1 is 00010. Performing mask2 |= 00010 updates mask2 to 100010.

Then, we iterate through nums2, updating mask2 for each digit: ○ For digit 5, the binary representation of 1 << 5 is 100000. Performing mask2 |= 100000 results in mask2 = 100000.

Example Walkthrough

Initializing Masks:

Let's illustrate the solution approach using a small example:

Suppose we have two arrays: nums1 = [4, 3] and nums2 = [5, 1].

• We look for common digits by performing mask = mask1 & mask2, resulting in mask = 000000. Since there are no common digits

(mask = 0), we move on to extracting the smallest non-common digit from each array.

based indexing, so a = 3. • Similarly, for mask2 equaling 100010, (mask2 & -mask2).bit_length() - 1 returns the bit position of the last 1, which is 1 in this

Extracting Smallest Non-Common Digits:

The smallest of these two is 13.

mask1 = mask2 = 0

for num in nums1:

for num in nums2:

if common_mask:

mask1 |= 1 << num

This example demonstrates how the bit manipulation method outlined in the solution approach can be applied to efficiently solve the given problem.

So, the smallest number comprising at least one digit from each array using the bit operation method is the number 13.

• Since there's no common digit, we create two possible numbers by combining a and b: a * 10 + b = 31 and b * 10 + a = 13.

• The smallest digit in nums1 can be found by isolating the last 1 in mask1, which is 00001000. We get its bit position using (mask1 &

12 mask2 |= 1 << num 13 14 # Create a mask to find common elements by applying bitwise AND on mask1 and mask2. 15 common_mask = mask1 & mask2

Find the smallest number by isolating the lowest set bit and calculating its index.

Initialize two bit masks to represent the numbers present in nums1 and nums2.

Iterate over the first list and update the mask1 to track the numbers.

Iterate over the second list and update the mask2 to track the numbers.

If no common number is found, find the smallest number from each list.

If there is a common number, return the smallest one.

return (common_mask & -common_mask).bit_length() - 1

- # Find the lowest set bit for each mask to get the smallest number from each list. smallest_num1 = (mask1 & -mask1).bit_length() - 1 smallest_num2 = (mask2 & -mask2).bit_length() - 1 # Compute the smallest two-digit number using the smallest elements from both lists. # Because we need the lexicographically smallest number, we calculate both combinations.
- # Return the smallest two-digit number. return smallest_combination

 $smallest_combination = min(smallest_num1 * 10 + smallest_num2, smallest_num2 * 10 + smallest_num1)$

After creating the bitmasks, the subsequent operations involving bitwise AND and finding the rightmost set bit also execute in constant time, as they are not dependent on the size of the input but instead on the fixed size of an integer (typically 32 or 64 bits in modern architectures).

The space complexity of the code is 0(1). This constant space usage comes from the fact that no matter the size of the input lists, the code only uses a fixed number of integer variables (mask1, mask2, mask, a, and b). These variables do not scale with the input size,

contain a common digit, we can use just this digit as it fulfills the criteria of containing at least one digit from each array while

In this approach, we compare each digit from one array to every digit in the other array to check for common digits. If we find a

sized structure (since digits only go from 0 to 9), and we check each digit against this structure. The moment we find a common digit, we conclude the search and return it. If there are no common digits, we again proceed to find the smallest two digits and concatenate them in both possible ways, returning the smaller resulting number.

Solution Approach contains at least one digit from each array (nums1 and nums2). Here's a breakdown of this approach:

Finding Common Digits: Once we have our bitmasks, we check for common digits by performing a bitwise 'AND' operation between mask1 and mask2 (mask = mask1 & mask2). If any common digit exists, mask will not be zero. The common digit can be

in both masks mask1 and mask2 to get the smallest digits a and b from each array. We use the bitwise 'AND' operation with the two's complement of each bitmask to isolate the last 1 bit ((mask1 & -mask1).bit_length() - 1 and (mask2 & $mask2).bit_length() - 1).$

- This bit manipulation method is very efficient because it reduces the problem of finding digits and comparing them to simple bitwise operations, which are performed quickly at the hardware level. Instead of needing to store and search through a hash table or array, this approach makes use of existing integer operations to encode the same information in a very compact space. The space complexity of this algorithm is constant, 0(1), because the bitmasks do not grow with the size of the input arrays. The
- We iterate through nums1, updating mask1 for each digit:
- At this point, we have mask1 = 11000 and mask2 = 100010. **Finding Common Digits:**
- -mask1).bit_length() 1. In this case, mask1 & -mask1 equals 00001000, whose bit_length() is 4, but we subtract 1 for zerocase. So, b = 1. Forming the Smallest Number:
- Python Solution 1 class Solution: def minNumber(self, nums1: List[int], nums2: List[int]) -> int:

> Time and Space Complexity The time complexity of the code is 0(m + n) where m is the length of nums1 and n is the length of nums2. This is because the code iterates through each of the two lists exactly once to create two bitmasks. The bitwise OR operations inside the loops take constant time per element.

resulting in constant space consumption.
