659. Split Array into Consecutive Subsequences

Hash Table Heap (Priority Queue)

# **Problem Description**

**Greedy** Array

Medium

You're given a sorted integer array nums with non-decreasing elements. Your task is to check whether you can split the array into one or more subsequences where each subsequence is a strictly increasing consecutive sequence (each number is exactly one more than the previous one), and each subsequence must contain at least three numbers. If it's possible to do such a split, you should return true, otherwise return false. Consider the array [1,2,3,3,4,5], it can be split into two subsequences [1,2,3] and [3,4,5] which satisfy the conditions

above, so the output is true. Intuition

The intuition behind the solution is to use a greedy approach. We try to build all possible subsequences by iterating through the

### nums array, and for each element, we want to extend a subsequence that ends at the element before the current one (this would

To make this efficient, we use a hashmap to store the ends of the subsequences, mapping the last element of a subsequence to a min-heap of lengths of all subsequences ending with that element. Min-heaps are used because we want to extend the shortest subsequence available, which minimizes the chance of not being able to create valid subsequences as we add more elements.

make it a consecutive sequence). If such a subsequence does not exist, we'll start a new subsequence.

If at any point we can extend a subsequence, we'll pop the length of the shortest subsequence from the min-heap of the predecessor of the current element, increment the length (since we're adding the current element to it), and push the new length to the current element's min-heap. If there is no subsequence to extend, we start a new one by pushing a length of 1 to the current element's min-heap.

In the end, we go through the hashmap and check if any subsequence lengths are less than 3. If we find any, that means we have an invalid subsequence, and we return false. If all lengths are 3 or greater, we return true as we've successfully created valid subsequences. Thus, the key to this approach is maintaining and updating the min-heaps efficiently as we move through the array.

The implementation uses a hashmap (defaultdict from the collections module in Python) paired with a min-heap (from the

heapq module) for each unique key. These data structures are crucial as they store subsequences' lengths efficiently and allow

Here's the approach broken down into steps:

#### ∘ For each number v in nums, check if there is a subsequence that ended just before v (i.e., at v − 1). If such a subsequence exists (if h := d[v - 1]:):

**Solution Approach** 

 $\circ$  Pop the length of the shortest such subsequence from the min-heap at v - 1 (using heappop(h)). Increment this length by 1, since v will extend this subsequence (heappop(h) + 1). Push the new length to the min-heap for v to keep track of this extended subsequence (heappush(d[v], heappop(h) + 1)).

Initialize a new subsequence with a single element v by pushing 1 to the min-heap for v (heappush(d[v], 1)).

At each step, subsequences are either extended or started, and the d hashmap tracks these actions efficiently using min-heaps.

If no such subsequence exists (else:):

for quick retrieval and update operations.

Iterate over the sorted nums array:

After processing all the elements in hums, check if any subsequence is invalid (less than 3 elements). The final check (return

• not v checks if the min-heap is empty, which would mean no invalid subsequence was found for that key, so a True is implied.

all(not v or v and v[0] > 2 for v in d.values())) iterates over all the min-heaps stored in the hashmap:

Following the steps outlined in the solution approach:

We start by iterating through the sorted array nums = [1, 2, 3, 4, 4, 5].

The hash map d now looks like this: {1: [1], 2: [2], 3: [3], 4: [4, 1], 5: [2]}.

4, 4, 5] would be False since not all subsequences contain at least three numbers.

implying a valid subsequence.

**Example Walkthrough** 

d[1] = [1].

Let's walk through a smaller example to illustrate the solution approach using the array [1, 2, 3, 4, 4, 5].

• v and v[0] > 2 checks if the min-heap is not empty and the length of the shortest subsequence is greater than 2 for that particular element,

If all min-heaps validate the condition (meaning all subsequences are of length 3 or more), True is returned, otherwise False.

Next element 2, there is a subsequence ending at 1 so we take its length 1, increment by one, and push 2 into min-heap for 2: d[2] = [2].

For the first element 1, there is no previous subsequence, so we initiate a subsequence by pushing 1 into min-heap for 1:

For the next element 3, there is a subsequence ending at 2, so again we take its length 2, increment it by one, and push 3

The next element is 4 again. Since we cannot extend the subsequence ending in 3 anymore (as it's already been extended),

## Now we encounter the first 4. A subsequence ends at 3, so we take the length 3, increment it, and push 4 to the min-heap

for 4: d[4] = [4].

Solution Implementation

from collections import defaultdict

for num in nums:

else:

import java.util.HashMap;

import java.util.PriorityQueue;

} else {

class Solution {

**Python** 

import heapq

class Solution:

into min-heap for 3: d[3] = [3].

we start a new subsequence with 4: d[4] = [4, 1].

For 5, the subsequence length is 2, which is less than 3.

# Iterate through all numbers in the provided list

heapq.heappush(sequence\_lengths[num], 1)

# Check all the (non-empty) sequences in the dictionary

# Pop the shortest sequence that ends with num - 1

Map<Integer, PriorityQueue<Integer>> seqEndMap = new HashMap<>();

shortest sequence = heapq.heappop(sequence lengths[num - 1])

heapq.heappush(sequence\_lengths[num], shortest\_sequence + 1)

# Start a new sequence with the current number (with length 1)

# Add the current number to this sequence (incrementing its length)

if sequence lengths[num - 1]:

7. The final element 5 has the potential to extend the subsequence ending with the second 4. We pop 1, increment it to 2, and push it to min-heap for 5: d[5] = [2].

- 8. Looking into each min-heap, we see the following lengths: • For 1, the subsequence length is 1, which is less than 3. This is a problem, as we need all subsequences to be at least length 3. • For 4, one of the subsequences has a length 1, which is also less than 3.
- This example demonstrates the process of iterating through the numbers, trying to extend existing subsequences using a minheap and a hashmap, and finally verifying that all subsequences have met the minimum length requirement.

These insights infer that there are subsequences that do not meet the requirement. Therefore, the output for the array [1, 2, 3,

Time and Space Complexity

**Time Complexity:** The time complexity of the code is determined by: 1. The iteration through each number in the list (for v in nums), which takes 0(n) time where n is the length of nums. 2. The heap operations (heappush and heappop) which are  $O(\log(k))$  where k is the number of entries in the heap at any time.

The given Python code performs an operation on a list of integers nums to determine if it is possible to split nums into

return all(len(sequence) == 0 or (len(sequence) > 0 and sequence[0] > 2) for sequence in sequence\_lengths.values())

### For each number in nums, the code might do a heappush and a heappop, each of which can take up to 0(log(k)) time. Note that k can potentially be as large as n in the worst case when there are many different sequences being formed. However, since it's observed that each number in the array can only belong to one subsequence and hence k is related to the number of possible

**Space Complexity:** 

The final iteration to check if each subsequence has a length of more than 2 takes 0(m) where m is the number of distinct elements in nums.

The space complexity of the code is given by: 1. The extra space used by the dictionary d which holds a heap for each possible terminal value of a subsequence, leading to 0(m) where m is

Putting this all together, the overall time complexity is 0(n log(k)) with the note that k tends to be smaller than n and is related

2. The heaps themselves, which together contain all n numbers, giving O(n). Since both the dictionary and the heaps need to be stored, their space complexities are additive, leading to a total space complexity of O(n + m). In the worst case, each element is unique so m could be as large as n, making the space complexity 0(n).
