1836. Remove Duplicates From an Unsorted Linked List

Problem Description

Hash Table

Medium

Linked List

more than once. Once we have identified such values, we are then to delete all the nodes containing any of those values from the linked list. The goal is to return the linked list after we've made all the necessary deletions.

In this problem, we are given the head of a singly <u>linked list</u>. Our task is to find all the values within this linked list that appear

Intuition To solve this problem, we need a way to track the frequency of each value present in the linked list. A common and efficient way to do this is by using a hash table, also known as a dictionary in Python, where the keys are the values from the linked list and the

linked list.

corresponding values are the counts of occurrences for each key. The solution approach involves two main steps. First, we need to traverse the entire linked list to populate the hash table with the correct counts for each value. With the completed hash table, we can then identify which values appear more than once in the

In the second step, we need to traverse the <u>linked list</u> again and this time, delete nodes that have a count greater than one. This amounts to checking the hash table for the count of the current node's value. If it's greater than one, it means this value appears multiple times and hence the node should be deleted. We need to carefully update the next pointers of the nodes that are not

deleted to ensure we have a properly linked list at the end. A dummy node is typically used as an anchor to manage the head of the list during deletion, especially in cases where the head node itself might need to be deleted. This dummy node initially points to the head of the list, and we start our iteration from the head while keeping track of the previous node as well. If a node needs to be deleted, we can bypass it by setting the next pointer of the previous node to the current node's next. If a node doesn't need to be deleted, we just move the previous pointer to the

current node. After iterating through the entire list and making necessary deletions, the dummy's next pointer points to the head of the modified list, which we return as the final result. **Solution Approach**

The implementation of the solution begins with importing Counter from the collections module in Python. The Counter class

provides a convenient way to count hashable objects. It is essentially a dictionary where elements are stored as dictionary keys

Initialize the Counter: An instance of the Counter is created, which will keep track of the number of occurrences of each element in the list. This is done by the line cnt = Counter().

the list (cur.next).

Example Walkthrough

our solution approach, here's an example walkthrough:

Look at cur node with value 4, cnt [4] > 1, it is a duplicate, so we bypass it.

cur moves to the second 2, which is bypassed, as cnt[2] > 1.

and their counts are stored as dictionary values.

Here's the step-by-step breakdown of the implementation:

First Pass - Count the Occurrences: The first traversal of the list occurs here, fulfilling the responsibility of counting occurrences of each value. We continue traversing the list until we reach the end (cur is None). During the traverse, we increment the count of the current value cur. val by doing cnt[cur.val] += 1. This forms the frequency mapping required to identify duplicates.

Setup the Dummy Node and Pointers: A dummy node is created with ListNode(0, head). This node is a placeholder to help manage deletions, especially when the head of the list might need to be deleted. The pre pointer is set to the dummy node and cur is reset to head.

Second Pass - Delete Duplicates: The list is traversed again. This time we have our frequency map ready, and hence for each node, we check if its value appears more than once by verifying cnt[cur.val] > 1. If this condition holds, it means the node is a duplicate and should be removed from the list. To delete the current node cur, we set the next pointer of the previous node pre to the next of the current, effectively bypassing the current node in the list. However, if the current node's value does not appear more than once, we need to keep it, and simply update the pre pointer

to reference the current node. After either of these checks is performed, we move the current pointer cur to the next node in

Return Modified List: After the traversal is complete and we have erased all the nodes that had duplicate values, the list is

now modified. The dummy next holds the reference to the new head of the list, which is returned as the final result. This algorithm effectively solves the problem using O(n) time complexity for the two traversals and O(n) space complexity for the counter.

Let's assume we have a singly linked list with the following values: $3 \rightarrow 4 \rightarrow 4 \rightarrow 2 \rightarrow 3 \rightarrow 1 \rightarrow 2$.

> 4 -> 2 -> 3 -> 1 -> 2, with pre pointing to dummy and cur pointing to the first node with value 3.

cur now points to 1, since cnt[1] == 1, it's not a duplicate, pre is updated to reference this node.

Second Pass - Delete Duplicates: We begin traversing the list again. Here's how we process each node:

Initialize the Counter: We start by creating an empty Counter object: cnt = Counter(). First Pass - Count the Occurrences: We traverse the list and count the occurrences of each value. The counter after this pass will look like this: $cnt = \{3: 2, 4: 2, 2: 2, 1:1\}$.

Setup the Dummy Node and Pointers: We create the dummy node and set up our pointers. Now, we have dummy -> 3 -> 4 -

Our objective is to identify all values that appear more than once and then remove all nodes containing any such values. Following

Look at cur node with value 3, cnt[3] > 1, it is a duplicate, so we update pre.next to cur.next, bypassing the current 3. cur now points to the first 4.

List traversal is now complete.

Solution Implementation

from collections import Counter

self.val = val

self.next = next

value_counter = Counter()

dummy node = ListNode(0, head)

Definition for singly-linked list.

def __init__(self, val=0, next=None):

def deleteDuplicatesUnsorted(self, head: ListNode) -> ListNode:

Start with a dummy node that points to the head of the list.

'previous' will lag one behind 'current' as we traverse the list.

This simplifies edge cases such as deleting the head node.

Initialize two pointers, 'previous' and 'current'.

value_counter[current_node.val] += 1

current_node = current_node.next

if value_counter[current.val] > 1:

previous = current

previous.next = current.next

Python

class ListNode:

class Solution:

 cur now points to the second 4, we repeat the above step. cur now points to the first 2, and we bypass it, as cnt[2] > 1. cur now points to the second 3, and we bypass it, as cnt[3] > 1.

So, the dummy next is pointing to the node with value 1, which is now the head of our resulting list. Hence, after the algorithm finishes, the linked list that we return will only contain the node with value 1.

Return Modified List: At this point of the walkthrough, only the node with value 1 remains, and the updated list points to it.

Traverse the linked list to populate the counter with the frequencies of each value. current_node = head while current_node:

Create a Counter to keep track of the frequency of each value in the linked list.

If the current node's value has a count greater than 1, it's a duplicate.

Therefore, skip this node by setting the previous node's next to be the next node.

If it's not a duplicate, move the 'previous' pointer up to be the 'current' node.

previous = dummy_node current = head # Traverse the linked list again, this time to remove duplicates.

while current:

else:

```

// If count is more than 1, it is a duplicate, remove it by updating the next pointer of the previous node

// If current value is not a duplicate, move previousNode pointer to the current node

values that occur more than once.

Return the modified list, starting from the dummy head's next value

current = current.next

return dummy_node.next

Time and Space Complexity

Time complexity: The time complexity of the code is O(n) where n is the length of the linked list. This is because each node in the list is visited exactly twice - once while counting the occurrences (first while loop) and once while removing duplicates (second while loop). Both operations for each node take constant time, so the total time is linear with respect to the number of nodes in the list.

The provided code aims to remove all nodes that have duplicate values from an unsorted singly-linked list. The algorithm works in

two passes. The first pass counts the occurrences of each value using a counter (cnt), and the second pass removes nodes with

Space complexity: The space complexity of the code is also O(n). This is due to the use of a counter (cnt) to store the occurrence count for each value present in the linked list. In the worst case, if all n nodes have unique values, the counter will need to store an entry for each value, resulting in O(n) space used.
