888. Fair Candy Swap

Problem Description

Alice and Bob each have a collection of candy boxes, with each box containing a certain number of candies. The total number of candies each of them has is different. Given two lists, aliceSizes representing the number of candies in Alice's boxes and bobSizes for Bob's boxes, the task is to find a pair of boxes (one from Alice and one from Bob) that they can exchange with each other so that they end up with the same total number of candies.

In other words, we need to find two values, one from each list, such that when Alice gives Bob the box with her value and Bob gives Alice the box with his value, the total candies they each have will be equal. The problem ensures that there is at least one such pair and asks us to return any one of them as a 2-element array: [Alice's box of candies, Bob's box of candies].

Intuition

If x is the amount of candies in the box Alice gives to Bob, and y is the amount in the box Bob gives to Alice, after the exchange, the total candies for both should be the same. If we denote sumA as the total candies that Alice has and sumB for Bob, the equation after the exchange would be: (sumA - x) + y = (sumB - y) + x

The solution to this problem relies on the concept of the exchange itself and the resulting equality of candy totals for Alice and Bob.

```
Which can be simplified to:
```

sumA - sumB = 2 * (x - y)

```
By rearranging the terms, we get the difference diff between the totals divided by 2 equals the difference between x and y:
```

diff = sumA - sumB

```
x - y = diff / 2
```

Given this, we can then iterate through Alice's boxes, and for each candy count a, we can calculate the corresponding count target

we can quickly check whether this target exists. Because Set operations in Python are O(1) on average, this check is efficient. If we find a match (target in Bob's Set), we return that pair [a, target] as our solution.

The fairCandySwap algorithm takes two lists of integers as input: aliceSizes and bobSizes. Each list represents the sizes of candy

= a - diff / 2 that we're looking for in Bob's boxes. Then by utilizing a Set in Python that contains all of Bob's candy box counts,

Solution Approach

boxes for Alice and Bob, respectively.

The approach starts by calculating the difference in total candy amounts between Alice and Bob and dividing it by 2. The division by 2 comes from rearranging the equation sumA - sumB = 2 * (x - y) into x - y = (sumA - sumB) / 2. This value is stored in the variable diff, signifying the amount of candy that needs to be compensated for in the swap to balance the totals:

1 diff = (sum(aliceSizes) - sum(bobSizes)) >> 1 In the code, the right-shift operator >> 1 is used as an efficient way to divide the difference by 2.

```
Next, a Set called s is created from Bob's list of candy sizes. Sets allow for constant time complexity (O(1)) checks for the existence
```

of an element, which is leveraged later: 1 s = set(bobSizes)

The algorithm then iterates through the list of Alice's candy sizes. For each candy size a, it computes the corresponding candy size target that Bob needs to provide:

```
return [a, target]
```

target = a - diff

if target in s:

1 for a in aliceSizes:

In summary, the algorithm follows these steps: 1. Calculate the difference diff between Alice's and Bob's total candy amounts and divide it by 2. 2. Create a Set from Bob's candy sizes for efficient lookup.

This loop checks whether the calculated target exists in Bob's set of candy sizes (s). If it does, that means there is a pair of candy

boxes [a, target] that can be swapped to ensure both Alice and Bob end up with the same total amount of candy. The algorithm

4. Check if target exists in Bob's Set.

then returns this pair as soon as it's found.

5. Return the first pair [a, target] where target is in Bob's Set.

3. Iterate through Alice's candy sizes, calculate the corresponding target size for Bob.

- This approach leverages arithmetic to determine the needed exchange and a Set for efficient lookup, making the solution both straightforward and performant.
- Let's assume we have the following candy box sizes for Alice and Bob:

Here's how we would use the solution approach to find the pair of boxes to be exchanged:

bobSizes = [2, 4]

Example Walkthrough

aliceSizes = [1, 2, 5]

 \circ sumA = 1 + 2 + 5 = 8

1. Calculate the total candies and the difference diff:

```
\circ sumB = 2 + 4 = 6
Therefore, the difference diff = (sumA - sumB) / 2 = (8 - 6) / 2 = 1.
```

s = set(bobSizes), which gives us $s = \{2, 4\}$.

We sum up the candies in Alice's and Bob's boxes:

```
2. Create a Set of Bob's candy sizes for efficient lookup:
```

For a in [1, 2, 5], we calculate target as follows:

```
    When a = 1, target = 1 - diff = 1 - 1 = 0. Since 0 is not in set s, we continue.

    When a = 2, target = 2 - diff = 2 - 1 = 1. Since 1 is not in set s, we continue.

\circ When a = 5, target = 5 - diff = 5 - 1 = 4.4 is in set s.
```

3. Iterate through Alice's candy sizes to find the corresponding target for Bob:

and they will both end up with 7 candies total, achieving a fair candy swap.

bob_sizes_set = set(bob_sizes)

for candy_size_alice in alice_sizes:

if (bobCandies.contains(targetSize)) {

// If no fair swap is possible, return null

// Return the pair that represents the fair swap

return new int[]{aliceCandySize, targetSize};

4. Return the first successful pair [a, target]:

because any swap should compensate for half of the total size difference. size_difference = (sum(alice_sizes) - sum(bob_sizes)) // 2 # Create a set of Bob's candy sizes for constant-time look-up

def fairCandySwap(self, alice_sizes: List[int], bob_sizes: List[int]) -> List[int]:

Compute the difference in candy sizes between Alice and Bob, divided by 2

Calculate the target size of Bob's candy that would make the swap fair

Iterate through Alice's candy sizes to find the fair swap

Since we found 4 (which is target) in Bob's set when Alice's box size was 5, the pair [5, 4] is returned.

target_size_bob = candy_size_alice - size_difference 14 15 # Check if Bob has a candy of the target size if target_size_bob in bob_sizes_set: 16 # Return a list containing Alice's candy size and the corresponding 17 # Bob's candy size for a fair swap

So, by utilizing the solution approach, we find that Alice can give Bob a box of 5 candies, and Bob can give Alice a box of 4 candies,

return [candy_size_alice, target_size_bob] 19 20 21 # Note: no need for an explicit return statement for no match scenario 22 # because the question implies there is always a valid swap. 23

the variables use constant space.

Typescript Solution

26 return []; 27 } 28 Time and Space Complexity

Time Complexity: The time complexity of the given code is O(A + B), where A is the number of elements in aliceSizes and B is the number of elements in bobSizes. Here's the breakdown: calculating the sum of both arrays takes O(A) and O(B) time respectively; creating the set s of bobSizes takes O(B) time; and the for loop runs for every element in aliceSizes, giving another O(A). Since set

the sum of these operations, which simplifies to O(A + B). Space Complexity: The space complexity of the code is O(B). This is because we create a set s consisting of all elements in bobSizes, which takes up space proportional to the number of elements in bobSizes. No other significant space is used as the rest of

look-up is 0(1) on average, checking if target is in s does not significantly add to the complexity. Thus, the overall time complexity is
