

Problem Description

In this task, you are given a DataFrame students that consists of three columns: student_id, name, and age. The student_id column holds integer values representing the unique ID of each student, name holds object values representing the names of the students which can be strings, and age contains integer values representing the students' ages. It has been noted that some entries in the name column are missing. The goal is to write a Python function that will process this DataFrame and remove any rows where the name is missing.

algorithms that expect non-null values. Handling missing data is therefore a common preprocessing step. The result after processing should only include rows where the name has a valid non-null value. The expected output is a DataFrame that no longer contains the rows with the missing name values, preserving all the other rows.

A missing value in a DataFrame can cause issues in data analysis and may not be suitable for some types of computations or

Intuition

Pandas (the library being used) provides several methods for handling missing data. One of those methods is notnull(), which

To solve this problem, we need to consider an operation that can filter out rows based on the presence of missing values.

returns a Boolean series indicating whether each value in a DataFrame is not null. By applying notnull() to the name column, we get a series where each row has either True if the name is present or False if the name is missing. We then use this series to filter the original DataFrame by passing it inside the square brackets []. This is known as boolean

indexing and it will only select the rows from students where the corresponding value in the boolean series is True. As a result, all

rows with True will be kept and those with False will be removed. The provided function dropMissingData simply performs this operation. It returns a new DataFrame without those rows that had missing name values, thus achieving the desired preprocessing step needed to clean the data.

Solution Approach

and analysis in Python. The solution approach is straightforward and involves the following steps:

1. Use the notnull() method provided by Pandas to check which rows in the name column have non-missing data. This method is applied column-wise and generates a boolean mask where each value corresponds to a row in the DataFrame.

The implementation of the solution utilizes the capabilities of the Pandas library, which is specifically designed for data manipulation

- 2. This boolean mask has True values for rows where name is not null (i.e., not missing) and False for rows where name is null. 3. Apply the boolean mask to the DataFrame using the square bracket notation []. This is a form of boolean indexing, a powerful
- feature provided by Pandas that allows for selecting data based on actual values rather than relying on traditional index locations.
- 4. The DataFrame gets filtered: only rows with True in the boolean mask will be kept, effectively dropping the rows where name is missing. The key data structure used in this solution is the DataFrame, which can be imagined as a table or a spreadsheet-like structure
- Pandas' methods. The algorithm pattern utilized is known as filtering. The notnull() method is crucial in this pattern as it provides the essential step of

where data is organized into rows and columns. Each column can be of a different type and can be accessed or modified easily using

1 def dropMissingData(students): # Step 1: Generate a boolean mask for non-missing 'name' values valid_names_mask = students['name'].notnull()

In summary, here's the pseudocode for the implemented solution, translating the steps into code operations:

```
return clean_students
This function dropMissingData() when called with a DataFrame as an argument, returns a new DataFrame devoid of any rows with
missing name values. The returned DataFrame is suitable for further data processing steps where complete information is required.
```

Step 2: Apply the mask to the DataFrame, keeping only valid rows

distinguishing the data to keep from the data to discard.

clean_students = students[valid_names_mask]

Let's walk through a small example to illustrate the solution approach described above.

name

Null

Charlie

student_id

2

3

3

3

5

Example Walkthrough

20 Alice

Suppose we have the following students DataFrame:

age

22

21

20

21

23

True

True

False

student_id	name	age	name.notnull()	
1. We apply	the notnul	l() me	thod to the name col	umn to create a boolean mask. This gives us:
Following the	steps of th	e soluti	on:	
In this DataFra	me, we ca	n see tl	hat the name field is	missing for student_id 2 and 4 (represented by Null for visualization purposes).
5	Eve	20		
4	Null	23		

Alice

Charlie

Charlie

Eve

Null

22 Null **False**

5	Eve	20	True			
3	Lve	20	True			
2. Now we have a boolean mask that indicates True for rows with a valid name and False for rows with a missing nar						
3 Nevt we f	ilter the or	iginal D	ataFrame by apply			
rows that h		200				
			1			
student_id	name	age				
1	Alice	20				

21

20

valid_names_mask = students['name'].notnull()

3 Charlie 21

Eve 20

And here is the actual code that would perform this filtering:

Assume students is a DataFrame initialized with the provided data

4. The resultant filtered DataFrame clean_students contains only the rows where name is not null.

student_id name age Alice 20

def dropMissingData(students: pd.DataFrame) -> pd.DataFrame:

Drop rows from the 'students' DataFrame where the 'name' column has missing values.

// A class to demonstrate the equivalent operation in Java, albeit with plain data structures

* Drops rows from a list of rows where the 'name' column has missing values.

List<Map<String, String>> cleanStudents = dropMissingData(students);

* @param students List of Map entries representing rows of a student DataFrame.

```
clean_students = students[valid_names_mask]
   print(clean_students)
The expected output after running the code would be the clean_students DataFrame, which no longer contains the rows where the
name was missing:
```

Python Solution

import pandas as pd

import pandas as pd

notnull() is used to select the rows where 'name' column is not NA/NaN clean_students = students[students['name'].notnull()] return clean_students

This cleaned DataFrame is now ready for further analysis or processing without the problem of handling missing name values.

```
Java Solution
1 import java.util.ArrayList;
  import java.util.List;
```

import java.util.stream.Collectors;

public class DataFrameUtils {

import java.util.Map;

```
12
        * @return List of Map entries after removing rows with missing 'name'.
13
       public static List<Map<String, String>> dropMissingData(List<Map<String, String>> students) {
14
15
           // Use stream to filter out any rows where the 'name' value is null or empty
           List<Map<String, String>> cleanStudents = students.stream()
16
17
                    .filter(row -> row.get("name") != null && !row.get("name").isEmpty())
                    .collect(Collectors.toList());
18
           return cleanStudents;
19
20
21
22
       // Usage example
23
       public static void main(String[] args) {
24
           List<Map<String, String>> students = new ArrayList<>();
           // Populate the list 'students' with data
```

// ...

// ...

```
C++ Solution
 1 #include <iostream>
 2 #include <vector>
 3 #include <optional>
   #include <algorithm>
   // Define a structure for Student which holds an optional name and other attributes
   struct Student {
       std::optional<std::string> name;
       // Add other attributes for Student if needed
10 };
11
12 // Function to drop rows from a vector of Student structs where the 'name' is missing
  std::vector<Student> DropMissingData(const std::vector<Student>& students) {
       // Create a new vector to store students with valid names
14
       std::vector<Student> cleanStudents;
15
16
       // Use the copy_if algorithm to copy only those students whose name is present
17
       std::copy_if(
18
19
           students.begin(), students.end(),
           std::back_inserter(cleanStudents),
20
            [](const Student& s) {
               return s.name.has_value(); // Check if 'name' is not missing
23
24
       );
25
26
       // Return the new vector with all students that have a name
27
       return cleanStudents;
28 }
29
   // Assuming you have some method to populate the students vector
   std::vector<Student> populateStudents();
32
   int main() {
       // Populate your students vector (assuming this function is implemented)
34
       std::vector<Student> students = populateStudents();
35
36
37
       // Use the DropMissingData function to remove students without a name
       std::vector<Student> studentsWithNames = DropMissingData(students);
38
39
       // Now studentsWithNames contains only students with non-missing names
40
```

interface Student {

as 0(n).

```
name?: string; // The '?' denotes that the 'name' property is optional and can be undefined
     // include other student properties as needed
   function dropMissingData(students: Student[]): Student[] {
     // Drop objects from the 'students' array where the 'name' property is missing or undefined
     let cleanStudents: Student[] = students.filter(student => student.name != null);
     // The 'filter' method goes through each student and keeps those where 'name' is not 'null' or 'undefined'
10
     return cleanStudents;
12
13
Time and Space Complexity
```

missing. Below is the time and space complexity of the provided function:

// Process the clean list as required...

Time Complexity: The function uses notnull() method combined with the DataFrame indexing to filter out rows with non-null 'name' values. The time complexity of notnull() and the boolean indexing in pandas is linear with respect to the number of rows, n, since each element in the 'name' column needs to be checked once for a null condition. Therefore, the time complexity can be expressed

The given function dropMissingData is intended to remove rows from a pandas DataFrame where the values in the 'name' column are

Space Complexity: Since pandas often uses views instead of copies, the space complexity for the filtering operation is 0(1). However, if a copy is created during the operation due to pandas internal optimizations based on the DataFrame size or data types, the space complexity could be O(n) as a new DataFrame object is created to hold the filtered data. In the worst case, we consider the space complexity to be O(n).
