Problem Description

The given problem requires us to conduct a postorder traversal on a given n-ary tree and return a list of the values of its nodes. In postorder traversal, we visit the nodes in a left-right-root order for binary trees, which extends to child1-child2-...-childN-root order in the case of n-ary trees, where N can be any number of children a node can have.

N-ary trees differ from regular binary trees as they can have more than two children. In the serialization of such a tree for level order

traversal, each set of children is denoted, and then a null value is used to separate them, indicating the end of one level and the beginning of another.

To solve this problem, we can utilize a stack to simulate the postorder traversal by considering the following points:

Intuition

2. We start by pushing the root node onto the stack.

3. When popping from the stack, we add the node's value to the answer list and then push all of its children onto the stack. This push operation is done in the original children order, which means when we pop them, they will be in reversed order because of

1. A stack data structure follows last in, first out (LIFO) principle, which can be leveraged to visit nodes in the required postorder.

- the LIFO property of the stack.
- 4. The traversal continues until the stack is empty. 5. After we've traversed all nodes and have our answer list, it will be in root-childN-...-child1 order. To obtain the postorder traversal, we need to reverse this list before returning it. The reversal step is essential to have the nodes in the child1-child2-...childN-root order.
- By following the described steps, we visit each node's children before visiting the node itself (as per postorder traversal rules) by effectively leveraging the stack's characteristics to traverse the n-ary tree non-recursively.

The implementation of the postorder traversal for an n-ary tree is done using a stack to keep track of the nodes. The following steps break down the solution approach:

Solution Approach

 We define a list named ans to store the postorder traversal. • Then, we check if the given root is None and immediately return ans if true, as there are no nodes to traverse. 2. Stack Preparation:

3. Traversal:

1. Initialization:

Since the stack follows LIFO order, children are appended to the list ans in reverse order with respect to how they were

We enter a while loop that continues as long as stk is not empty.

We initialize a stack named stk and push the root node into it.

- Inside the loop, we pop the topmost node from the stack and append its value to list ans. • We then iterate over the children of the popped node in their given order and push each onto the stack stk.
- added to the stack. 4. Final Step:
 - Upon completion of the while loop (when the stack stk is empty), we have all the node values in ans but in the reverse order

Let's illustrate the solution approach with a simple n-ary tree example:

of the required postorder traversal.

- To fix this, we simply reverse ans using ans [::-1] and then return it. By using this approach, we avoid recursion, which can be helpful in environments where the call stack size is limited. The use of a
- fashion. **Example Walkthrough**

stack allows us to control the processing order of nodes, thereby enabling the simulation of post-order traversal in an iterative

In this tree, node 1 is the root, node 2 has one child 5, node 3 has no children, node 4 has two children 6 and 7.

Define a list ans to store the postorder traversal.

2. Stack Preparation:

1. Initialization:

3. Traversal:

Following the solution steps:

Initialize a stack stk and push the root node 1 onto it.

Pop the topmost node from stk, which is node 1. Add its value to list ans.

Pop node 3 from stk, add its value to ans. No children to add here.

Pop node 6 from stk, add its value to ans. No children to add here.

node 2 is on top. • Pop node 2 from stk, add its value to ans, and push its child onto the stack (5). Pop node 5 from stk, add its value to ans. No children to add here.

Return the reversed list.

• Check if the root is None. If it is, return ans.

Start the while loop since stk is not empty.

• Pop node 4 from stk, add its value to ans, and push its children (7, 6) onto the stack. Pop node 7 from stk, add its value to ans. No children to add here.

def __init__(self, val=None, children=None):

def postorder(self, root: 'Node') -> list[int]:

Stack to keep track of nodes to visit

Pop a node from the stack

stack.append(child)

current_node = stack.pop()

Continue processing nodes until stack is empty

postorder_result.append(current_node.val)

for child in current_node.children:

Add the current node's value to the traversal result

return result; // Return the populated list as the result

 Now the stk is empty, exit the while loop. 4. Final Step: • At this point, ans is in reverse order of the required post-order traversal: [1, 4, 7, 6, 3, 2, 5].

Push the children of node 1 (4, 3, 2) onto the stack. Note: Push in reverse order of the children as stated in the Intuition, so

So using the stated steps, we successfully performed an iterative postorder traversal on the n-ary tree and the final output is [5, 2, 6, 7, 4, 3, 1].

• Reverse ans to get the correct postorder traversal: [5, 2, 6, 7, 4, 3, 1].

self.val = val self.children = children if children is not None else []

    * @returns An array of node values in post-order.
12
    */
```

Time and Space Complexity

complexity remains O(N).

return result;

function postorder(root: INode | null): number[] {

* @param node - The current node being visited.

for (const childNode of node.children) {

depthFirstSearchPostOrder(childNode);

// Initiate the post-order traversal from the root of the tree

const result: number[] = [];

if (node == null) {

result.push(node.val);

depthFirstSearchPostOrder(root);

// Return the result of the traversal

return;

// An array to store the result of the post-order traversal

const depthFirstSearchPostOrder = (node: INode | null) => {

* Helper function for depth-first search post-order traversal of the node tree.

* It recursively visits children first before the parent node then pushes the value to the result array.

// Loop through each child of the current node and recursively perform a post-order traversal

// After visiting the children, push the current node's value to the result array

// If the node is null, i.e., either the tree is empty or we've reached the end of a branch, return

• Time Complexity: Each node is visited exactly once, and all its children are added to the stack. Assuming the tree has N nodes, and let C be the maximum number of children a node can have. In the worst case, every node will be pushed and popped from

The given code implements a post-order traversal of an n-ary tree iteratively using a stack. Analyzing the complexity:

since every node is visited once, and C is a constant factor, the time complexity simplifies to O(N). • Space Complexity: The space complexity is determined by the size of the stack and the output list. In the worst case, if the tree is imbalanced, the stack could hold all nodes in one of its branches. Therefore, the space complexity is O(N) for storing the N nodes in the worst-case scenario. The list ans also stores N node values. Hence, when considering the output list, the total space

the stack once, and all of its children (up to C children) will be processed. Therefore, the time complexity is 0(N * C). However,

Therefore, the overall time complexity of the code is O(N) and the space complexity is O(N).
