330. Patching Array

Problem Description

The problem is focused on a concept called patching array. Given a sorted array of integer numbers nums and an integer n, the task is to modify this array (by potentially adding new numbers to it), so that every number in the set {1, 2, ..., n} can be expressed as the sum of some elements in the array. You need to find the minimum number of new numbers (patches) that you have to add to the array to achieve this.

In simple terms, the question asks: "What is the smallest amount of numbers we can add to nums so that we can create every integer from 1 up to n using sums of numbers in nums?"

Intuition

elements and the numbers we add (patch). The strategy is to start with the smallest possible range [1, 1] and then expand this range as far as possible until we can reach n.

The intuition behind this solution comes from the idea of exploring "ranges" of numbers that can be created using the current array

needing to patch the array (since every number up to x can be formed, adding nums[i] lets us now form every number up to x + nums [i]). Each time this happens, we take the next number in nums and adjust our range accordingly.

If the next number in the array (nums[i]) is within the current range we can reach (<= x), it helps us extend the range further without

However, when the next number in nums is beyond the current reach (nums[i] > x), we can't use it to expand our range and must add (patch) a new number. The most efficient number to add is the next number just after the current reach (x itself), which maximally extends the range by doubling it (since before the patch we could reach x - 1, after adding x, we can reach 2x - 1).

more, we've added enough patches and can stop the process, returning the number of patches as our answer.

The algorithm keeps track of the patches added and the current range that can be formed. When the range expands to include n or

The algorithm makes use of a greedy approach, as it always tries to extend the range as much as possible with each step by either

Solution Approach

using the next available number in nums or by patching the smallest number possible to increase the coverage range. Here is the step-by-step explanation of the implementation:

1. Initialize two pointers: x starts at one, representing the current smallest number that we want to make sure can be formed by

nums. i keeps track of the current position in the nums array, starting at zero.

- 2. Initialize ans to zero, which will keep track of the number of patches needed. 3. Start a while loop that continues as long as x is less than or equal to n. This is because we need to ensure that we can form all
- the numbers in the range [1, n].
- 4. Inside the loop, we check if we have not yet used all numbers in nums and whether the current number at nums [i] can be used to
- Thus, we update x to x + nums[i] and increment i, moving to the next number in nums. 5. If, however, the current number in nums is larger than x, it cannot be used to extend our range. At this point, we must add a patch. The patch will be x, doubling the current range we can reach (x <<= 1 is equivalent to x = x * 2). We also increment the ans

extend the range. If nums[i] is less than or equal to x, then it means we can use nums[i] to create new sums up to x + nums[i].

- since we've used a patch. 6. This process continues, either extending the range with the current numbers in nums or adding patches until x exceeds n.
- It is important to note that this algorithm runs efficiently because:

7. When the loop finishes, ans holds the minimum number of patches added to achieve the goal, and we return ans.

We only iterate through nums once.

We use a while loop that runs in O(log n) time in the worst case scenario (when patches are added until x exceeds n).

- We do not use any additional data structures, which keeps our space complexity at O(1).
- With this approach, we then can return the minimum amount of patches needed to nums to ensure that all numbers within the range
- [1, n] can be formed.

Example Walkthrough

Suppose we have an array nums = [1, 3] and we want to ensure we can form every number from 1 to n = 7 using sums of numbers

from nums. We want to find the minimum number of patches needed.

Let's illustrate the solution approach with a small example:

1. Initialize x to 1 (since we need to start forming sums from 1) and i to 0 (the index of the first number in nums). ans is also initialized to 0 as no patches have been added.

2. Start the while loop since $x = 1 \le n = 7$. 3. Inside the loop, check if i is within bounds of nums and if nums[i] $\ll x$. For the first iteration, nums[0] = 1 is equal to x = 1.

Therefore, we can use nums[0] to form numbers up to 1 + 1 = 2. Update x to 2 and increment i to 1.

- 4. Next, with x = 2 and nums[i] = 3, we can see that nums[1] can be used to extend the range. We update x to 2 + 3 = 5 and increment i to 2 (which is now beyond the bounds of nums).
- 5. With x = 5 and i out of bounds, we need to patch. The optimal patch is x itself, so we add 5 (the patch) to nums. The range extends to 5 + 5 = 10, which is beyond n = 7, so we update x = 10. Increase ans by 1, since we added a patch.

6. The while loop ends because x = 10 is now greater than n = 7. We can now form all the numbers from 1 to 7 using [1, 3, 5].

- 7. The ans has counted a single patch (5). Therefore, we return ans = 1.
- Through this process, we find that we only need to add one patch (the number 5) to the array [1, 3] to be able to form every number between 1 and 7 inclusively.

Initialize the smallest number that cannot be formed # by summing elements in nums up to index i missing_number = 1 8

12
13
               // If the condition above is not true, we need to add a patch (a new number)
14
               // That number is always the current maximum sum itself, which doubles the range of representable sums.
15
               patchesNeeded++; // Increment the patches needed
               currentMax *= 2; // Double the current max sum
       // Return the total number of patches needed
       return patchesNeeded;
Time Complexity:
```

16 17 18 19 20 21 22 23 } 24 Time and Space Complexity

can double at most $O(\log(n))$ times to exceed n. In each iteration, the algorithm performs a constant amount of work unless it's adding a number from nums, in which case it works in

0(1) time to add a number and move the i pointer. Since it moves through each element of nums at most once, the number of these

The algorithm loops while x is less than or equal to n. Within each loop, the code either adds a number from nums to x (if the current element in nums is less than or equal to x), or it doubles x (if there is no such element or all elements have been used). The key point is that x grows exponentially (either by adding a number from nums that's less than or equal to x or by doubling through patches). Hence, the number of times the loop can iterate is logarithmic in relation to n. Specifically, it will iterate O(log(n)) times because x

operations is bounded by the length of nums. Therefore, the total time complexity is O(len(nums) + log(n)).

The extra space used by the algorithm is constant, as it only uses a few variables (x, ans, i) and does not allocate any additional space that grows with the size of the input. Thus, the space complexity is 0(1).
