204. Count Primes

Problem Description

number greater than 1 that has no positive divisors other than 1 and itself.

The problem requires us to find the count of prime numbers less than a given integer n. Remember, a prime number is a natural

Intuition

the multiples of each number starting from 2. Once all multiples of a particular number are marked, we move on to the next

The solution is based on an ancient algorithm known as the "Sieve of Eratosthenes". The algorithm works by iteratively marking

unmarked number and repeat the process. Here's the step-by-step intuition: 1. We start with a boolean array primes where each entry is set to True, meaning we assume all numbers are primes initially.

2. Starting from the first prime number 2, we mark all of its multiples as False, since multiples of 2 cannot be primes.

- 3. We continue this process for the next unmarked number (which would be the next prime) and mark all of its multiples as False.
- 4. We repeat the process until we have processed all numbers less than n.
- 5. During the process, every time we encounter a number that's not marked as False, it means this number is a prime number, and we increment the counter ans.

This solution is efficient because once a number is marked as False, it will not be checked again, which greatly reduces the

Solution Approach The implementation of the countPrimes function follows the Sieve of Eratosthenes algorithm:

We initialize a list called primes filled with True, representing all numbers from 0 to n-1. Here, True signifies that the number

is assumed to be a prime number.

class Solution:

10.

if n < 2:

return 0

def countPrimes(self, n: int) -> int:

assume they are prime until proven otherwise:

primes = [True, True, True, True, True, True, True, True, True, True]

primes = [True, True, True, True, False, True, False, True, False, True]

We iterate over each number starting from 2 (the smallest prime number) using a for loop for i in range(2, n):. If the

number of operations needed compared to checking every number individually for primality.

- number is marked as True in our primes list, it is a prime, as it hasn't been marked as not prime by an earlier iteration (via its multiples).
- When we find such a prime number i, we increment our answer counter ans by 1, as we've just found a prime. To mark the multiples of i as not prime, we loop through a range starting from i*2 up to n (exclusive), in steps of i, using the inner loop for j in range(i + i, n, i):. The step of i makes sure we only hit the multiples of i.
- Continue the process until all numbers in our list have been processed.

Finally, we return ans, which now holds the count of prime numbers strictly less than n.

unnecessary checks, making this a classic and time-efficient solution for counting prime numbers.

For each multiple j of the prime number i, we set primes[j] to False to denote that j is not a prime.

- Throughout the process, the use of the array primes and the marking of non-prime numbers optimizes the approach and avoids
- Here is the final code that implements this approach:

primes = [True] * n ans = 0for i in range(2, n):

```
if primes[i]:
                 ans += 1
                 for j in range(i * i, n, i):
                     primes[j] = False
         return ans
  In this implementation, notice how we optimized the inner loop's starting point from i + i to i * i. Since any multiple k * i
  (where k < i) would already have been marked False by a prime less than i, it suffices to start marking from i * i.
Example Walkthrough
```

Following the steps outlined in the solution approach: We start by initializing a list primes that represents the numbers from 0 to 9. All the values are set to True, indicating we

Let's illustrate the solution approach with a small example where n = 10. We want to find the count of prime numbers less than

We start checking numbers from 2 (the smallest prime number). Since primes[2] is True, 2 is a prime number, so we increment our prime count ans.

False, affecting 6 and 9:

The prime count ans is now 2.

The prime count ans is now 3.

The prime count ans is now 4.

prime and increment ans.

Java

class Solution {

given integer n.

Solution Implementation

is prime = [True] * n

prime_count = 0

Count the number of primes

for current number in range(2, n):

if is prime[current number]:

Start from the first prime number, which is 2

is_prime[multiple] = False

Return the total count of prime numbers found

Now, we mark all multiples of 2 as not prime by setting their respective positions in the primes array to False. This will mark 4, 6 and 8 as not prime:

```
The prime count ans is now 1.
```

The next number is 3, which is also True in the primes list, so we increment and again. We then mark all multiples of 3 as

primes = [True, True, True, True, False, True, False, True, False, False]

```
Then we check 5, which is True. Therefore, we increment ans and mark its multiples (none within our range, as the first
would be 10, which is outside our range).
```

Continuing this process, we check 6 (marked as not prime), 7 (prime), and 8 (not prime). When we reach 7, we mark it as

Finally, we process 9 (marked as not prime) and the primes list won't change anymore as there's no need to mark further

multiples.

primes = [True, True, True, True, False, True, False, True, False, False]

Here's a visualization of the primes list after processing primes:

Our final prime count ans is 4. Therefore, there are 4 prime numbers less than 10.

prime_count += 1 # Increment count if current number is prime

for multiple in range(current number * 2, n, current_number):

// Use the Sieve of Eratosthenes algorithm to find all primes less than n

for (long long $j = (long long)i * i; j < n; j += i) {$

if (isPrime[i]) { // If the number is marked as prime

return primeCount; // Return the total count of primes found

* Counts the number of prime numbers less than a non-negative number, n.

* @return {number} The count of prime numbers less than n.

let isPrime: boolean[] = new Array(n).fill(true);

const countPrimes = (n: number): number => {

if (isPrime[i]) {

++primeCount;

++primeCount; // Increment the count of primes

for (int i = 2; i < n; ++i) { // Start at the first prime, 2, and check up to n

isPrime[j] = false; // Mark the multiple as not prime

* Implements the Sieve of Eratosthenes algorithm for finding all prime numbers in a given range.

* @param {number} n - The upper limit (exclusive) up to which to count prime numbers.

// Initialize an array of boolean values representing the primality of each number.

// Increment the prime counter when a prime number is encountered.

// Initially, all numbers are assumed to be prime (true), except for indices 0 and 1.

Mark multiples of the current number as not prime

The next number is 4, which is False in the primes list, so we skip it.

At the indices where primes list is True (excluding the indices 0 and 1 since we start counting primes from 2), those numbers are the primes less than 10, and we count them up to get our answer, which is 4. This is how the Sieve of Eratosthenes algorithm

works and the code from the solution approach implements this efficiently to count the number of prime numbers less than any

class Solution: def countPrimes(self. n: int) -> int: if n < 3: # There are no prime numbers less than 2</pre> return 0 # Initialize a list to track prime numbers. # True means the number is initially assumed to be prime

// Method to count the number of prime numbers less than a non-negative number, n. public int countPrimes(int n) { // Initialize an array to mark non-prime numbers (sieve of Eratosthenes). boolean[] isPrime = new boolean[n]; // Assume all numbers are prime initially (except index 0 and 1).

return prime_count

```
Arrays.fill(isPrime, true);
        // Counter for the number of primes found.
        int primeCount = 0;
        // Iterate through the array to find prime numbers.
        for (int i = 2; i < n; i++) {
            // Check if the number at current index is marked as prime.
            if (isPrime[i]) {
                // Increment the count as we found a prime.
                primeCount++;
                // Mark the multiples of the current number as non-prime.
                for (int j = i * 2; j < n; j += i) {
                    isPrime[j] = false;
        // Return the total count of prime numbers found.
        return primeCount;
