1312. Minimum Insertion Steps to Make a String Palindrome

String Dynamic Programming Hard

Problem Description

The task is to make a given string s a palindrome by inserting any number of characters at any position in the string. The objective is to achieve this with the minimum number of insertions possible. A palindrome is a word, number, phrase, or other sequences of characters that reads the same forward and backward, ignoring spaces, punctuation, and capitalization.

Intuition To solve this problem, we can use <u>dynamic programming</u>. The core idea is to build a solution using the answers to smaller subproblems. These subproblems involve finding the minimum number of insertions for all substrings of the given string and building upon those to arrive at the final answer.

We can define our subproblem as f(i, j), which is the minimum number of insertions to make the substring s[i...j] a palindrome. Therefore, f(0, n-1) (where n is the length of the string) will eventually be our answer for the whole string s. If the characters at the position i and j are the same, no insertion is needed, and f(i, j) will be the same as f(i+1, j-1) — the

number of insertions needed for the substring without these two matching characters. However, if they do not match, we have to do an insertion either at the beginning or the end of the substring. This means we have two options: either insert a character

matching s[j] before i or insert a character matching s[i] after j. Therefore, we'll take the minimum of f(i+1, j) and f(i, j-1) and add one (for the insertion we've made). We do this for all possible substrings starting from the end of the string and moving backward, which finally gives us the minimum number of insertions needed to make the entire string a palindrome. The Python solution provided implements this dynamic programming approach. It utilizes a 2D array f where f[i][j] holds the minimum number of insertions needed for the substring s[i...j]. We iterate through the string in reverse, gradually building up the solution for the entire string and returning f[0][-1], which represents the minimum number of insertions needed for the whole string s.

Solution Approach The solution to this problem applies dynamic programming because a direct approach would involve checking every possible insertion, leading to an inefficient exploration of the problem space. Dynamic programming, however, allows us to solve the

Here's a step-by-step explanation of the dynamic programming solution provided in the Reference Solution Approach:

problem more efficiently by breaking it down into overlapping subproblems and building up the answer.

minimum insertions needed for the inside substring).

complexity is a significant improvement over any naive approach.

[1-1] plus 1, which equals 1.

The final dp array f looks like this:

Solution Implementation

length = len(s)

def minInsertions(self, s: str) -> int:

Length of the input string

We use a 2D array f with dimensions n by n, where n is the length of the string s. f[i][j] will represent the minimum number of insertions required to make the substring s[i...j] a palindrome.

We initialize our dp array f with zeros because if i equals j, the substring is already a palindrome, and no insertions are needed. The main process occurs in a nested loop. We first iterate over i in reverse, starting from n-2 down to 0. The reason for

starting at n-2 is that the last character does not need any insertions to become a palindrome; it already is one on its own.

For each i, we then iterate over j from i+1 to n-1. This loop considers all substrings that start at index i and end at index j.

- Inside the nested loops, we check if the characters at index i and j are the same. If s[i] is equal to s[j], no additional insertions are needed to pair them up, so f[i][j] is set equal to f[i+1][j-1] (the
- If s[i] is not equal to s[j], we must insert a character. We can choose to align s[i] with some character to the right or to align s[j] with a character to the left. Therefore, f[i][j] is the minimum of f[i+1][j] and f[i][j-1] (the solutions to
- At the completion of the loops, f[0][-1] contains the answer. It represents the minimum number of insertions needed for the whole string, because it refers to the subproblem considering the entire string s [0...n-1].

By using dynamic programming, we avoid re-computing solutions to subproblems, which makes for an efficient solution. The

subproblems considering one side extended), plus one for the current insertion.

Reference Solution Approach leverages this overlapping of subproblems and optimal substructure properties common in dynamic programming problems.

Example Walkthrough Let's consider a short example with the string s = "abca". We want to find the minimum number of insertions required to make sa palindrome.

This algorithm has a time complexity of 0(n^2) due to the nested for loops iterating over all substrings, and a space complexity of

0(n^2) as well for storing the dp array. While the space complexity could be a concern for very long strings, the quadratic time

0 0

Fill in the dp array f starting from i = 2 down to 0. We need to loop from j = i+1 to 3. We ignore cases where i == j because

Initialize a 2D array f with dimensions 4×4, with all values set to 0, since the length of the string s is 4.

f[2+1][3] and f[2][3-1], which are both 0 at the moment, so after adding 1, f[2][3] = 1.

and f[1][3-1], which are 1 and 1 at this point, plus one for the insertion; we get f[1][3] = 2.

with an extra insertion. Since f[2][2] and f[1][1] are 0, we set f[1][2] to 1.

find the minimum number of insertions to make the string s a palindrome.

dp (Dynamic Programming) table where dp[i][j] will hold the

If the characters are different, we need one more

or at the end of the substring. We choose the option

that requires fewer insertions, hence the min function.

// Iterating from the character just after i up to the end of the string

dp[i][j] = Math.min(dp[i + 1][j], dp[i][j - 1]) + 1;

// The top-right corner of the DP matrix contains the answer for the whole string

// Fill the DP table starting from the bottom right and moving to the top left

dp[startIdx][endIdx] = dp[startIdx + 1][endIdx - 1];

insertion. We can insert either at the beginning

dp[i][j] = min(dp[i + 1][j], dp[i][j - 1]) + 1

The top-right corner of the dp table contains the answer

for the whole string, which is what we return.

for (int j = i + 1; j < length; ++j) {

if (s.charAt(i) == s.charAt(j)) {

if (s[startIdx] == s[endIdx]) {

dp[i][j] = dp[i + 1][j - 1];

those are already palindromes. Start with i = 2 and j = 3: s[2] = "c", <math>s[3] = "a". They do not match, so we need one insertion. We take the minimum from

1

2

0

0

0

3

3 0 Move to i = 1 and j = 2: s[1] = "b", s[2] = "c". They do not match, so we take the minimum of f[1+1][2] and f[1][2-1],

For i = 1 and j = 3, compare s[1] to s[3], which are "b" and "a". They're different, so f[1][3] is the minimum of f[1+1][3]

Now for i = 0 and j = 1: s[0] = "a", s[1] = "b". They're different, so we set f[0][1] to the minimum of f[0+1][1] or f[0]

- For i = 0, j = 2, we take the minimum of f[1][2] and f[0][1]. Both are 1 currently, so f[0][2] = 2. Finally, for i = 0, j = 3, we compare s[0] with s[3], which are the same. So, we set f[0][3] to f[1][2], which is 1.
- end of the string to get "abcba", which is a palindrome. This example demonstrates the procedure described in the solution approach, illustrating the steps taken to fill the dp array and

The top right cell f[0][3] gives us the minimum number of insertions needed, which is 1. In this case, we can insert a "b" at the

if s[i] == s[j]:

Length of the input string

length = len(s)

Time and Space Complexity The given Python code snippet is designed to find the minimum number of insertions needed to make the input string a palindrome. It uses dynamic programming to accomplish this task. The analysis of time and space complexity is as follows:

The time complexity of the code is $0(n^2)$, where n is the length of the input string s. This is because there are two nested loops:

- The outer loop runs backwards from n-2 to 0, which contributes to an O(n) complexity. • The inner loop runs from i + 1 to n, which also contributes to 0(n) complexity when considered with the outer loop.
 - Since each element f[i][j] of the DP matrix f is filled once and the amount of work done for each element is constant, the overall time complexity is the product of the two O(n) complexities.
 - The space complexity of the code is also $0(n^2)$. This is because a two-dimensional array f of size n * n is created to store
- intermediate results of the dynamic programming algorithm. So, both the space and time complexity are quadratic in terms of the length of the input string.
