# 2828. Check if a String Is an Acronym of Words

## **Problem Description**

The problem presents us with a list of strings called words, and another string s. We are asked to determine if s is an acronym for the words. An acronym in this context is defined as a string that can be formed by taking the first character of each string in words, in their respective order. For instance, given words = ["keep", "it", "simple", "stupid"], the string s = "kiss" would be an acronym of words because taking the first letter of each word in order produces "kiss".

To decide whether s is an acronym for words, we need to follow this rule and check if the concatenation of the first letter of each word in the words array is equal to s.

### Intuition

To solve this problem, the intuition is straightforward: we will sequentially take the first character from each string in the words array and concatenate them into a new string. Then, all we need to do is to compare this newly formed string to the given string s.

Here's the step-by-step intuition:

- 1. Initialize an empty string that will hold the concatenated first characters, or simply prepare to perform a comparison on-the-fly without creating a new string.
- 3. As we get each first character, either add it to the initialized string or compare it directly if not storing it.

2. Traverse the words list, and for each word, take its first character.

- 4. After processing all words, we either compare the created acronym string to s or if we've compared on-the-fly, ensure all
- characters matched. If the acronym we assembled matches s, we return true, indicating that s is an acronym of words. If not, we return false.

The provided Python solution uses a generator expression to create the acronym string by concatenating the first character of each word in words and then compares it directly to s. This approach is concise, memory-efficient, and takes advantage of Python's

expressive syntax. Solution Approach

## The implementation of the solution in Python is quite simple and utilizes few advanced concepts, but it demonstrates some of the

word.

processed.

core principles of programming — iteration and comparison. Algorithm: The algorithm followed here is a linear scan of the words list to create a string made up of the first character of each

- Data Structures: In the solution, the data structure used is the list (List[str]). This list holds the input strings that are
- Patterns: The pattern used here is a common Python idiom of using a generator expression within a string join method. A
- generator expression is an efficient way to iterate over data without the need for explicitly writing a loop or using additional memory for a list. It is commonly used for its concise syntax and because it generates elements on the fly; it is memory efficient. The implementation in Python can be walked through step-by-step:

1 return "".join(w[0] for w in words) == s

1. String Join and Generator Expression:

```
In this line of Python code, we have "".join(...), which is a method that takes an iterable and concatenates its elements
separated by the string it is called on—in this case, an empty string. This means no separator between the elements.
```

2. Generator Expression: The part inside the join method w[0] for w in words is a generator expression. It goes through each element win the list words.

For each element, it takes the first character w[0].

3. Comparison: Finally, the resulting string after concatenating all first characters is compared to the input string s. The operator == evaluates to

The elegance of this solution comes from its use of Python's generator expressions and the join method, which both play well

this list of words.

"n".

2 s = "nasa"

together to create a compact and efficient line of code. The approach is direct and specific to checking whether the acronym matches the input string without any unnecessary steps or calculations.

Example Walkthrough Let's walk through a small example using the solution approach to understand it better. Suppose we have the input list of words

True if both strings are equal, else False. This is the returned value of the isAcronym method.

#### Here's how the solution algorithm would process this example:

1. We start with an empty string (conceptually, as per the provided solution we do not explicitly create it) to collect the first letters. 2. We look at the first word "national", extract its first character "n", and add it to the acronym string. Our acronym string is now

["national", "aeronautics", "space", "administration"] and we want to verify whether the string s = "nasa" is an acronym for

3. Next, we take the first character of the second word "aeronautics" which is "a", and append it to our acronym string. The acronym string becomes "na".

4. We continue with the third word "space" and append its first character "s" to our acronym string, which now becomes "nas".

- 5. Finally, we extract the first character of the last word "administration" which is "a", and append it to our acronym string. The acronym string is now complete and equals "nasa".
- 6. We then compare this string to the given string s. Since "nasa" == "nasa", we return True. Using the actual Python solution from the solution approach:
- Upon executing the above, result would be True, showing that s is indeed an acronym for the provided list words.

1 words = ["national", "aeronautics", "space", "administration"]

# Import the typing module to use the List type annotation

def isAcronym(self, words: List[str], s: str) -> bool:

acronym = "".join(word[0] for word in words)

3 result = "".join(w[0] for w in words) == s

# in the list matches string 's'.

The elegant part of this algorithm is that we don't even need to store the acronym string. The comparison happens on-the-fly within the generator expression as it generates each first character and is immediately followed by the string concatenation and comparison with s. Thus, the process is both memory- and time-efficient.

# Create an acronym by joining the first letter of each word in the list 'words'

from typing import List # Define the Solution class class Solution: # Define the isAcronym method which takes a list of words and a string 's'. # It checks if the acronym formed by the first letters of the words

#### 13 # Compare the created acronym with the string 's' and return the result. 14 15 # This will return True if they match, False otherwise. return acronym == s 16

Python Solution

```
Java Solution
   class Solution {
       // Method to check if the given string 's' is an acronym of the list of words 'words'
       public boolean isAcronym(List<String> words, String s) {
           // StringBuilder to construct the acronym from the first letter of each word
           StringBuilder acronym = new StringBuilder();
           // Loop through each word in the list
           for (String word : words) {
               // Append the first character of each word to the acronym
 9
               acronym.append(word.charAt(0));
11
12
13
           // Compare the constructed acronym to the input string 's'
           // Return true if they are equal, otherwise return false
14
           return acronym.toString().equalsIgnoreCase(s);
15
16
18
```

#### bool isAcronym(std::vector<std::string>& words, std::string s) { std::string acronym; // Build the acronym from the first letters of 'words' // Iterate over each word in 'words' for (const auto& word : words) { // Ensure the word is not empty to avoid accessing out of range 12

if (!word.empty()) {

C++ Solution

1 #include <vector>

#include <string>

class Solution {

```
17
           // Compare the build acronym with the string 's' and return the result
18
           return acronym == s;
19
20 };
21
Typescript Solution
   /**
    * Checks if a provided string `s` is an acronym of the first letters of an array of words.
    * @param {string[]} words - An array of words to derive the acronym from.
    * @param {string} s - The string to compare with the acronym.
    * @returns {boolean} - Returns true if `s` is an acronym of the first letters of `words`, otherwise returns false.
    */
   function isAcronym(words: string[], s: string): boolean {
       // Map each word to its first character and join them to form the acronym
       const acronym = words.map(word => word[0]).join('');
11
12
       // Compare the formed acronym with the string `s`
       return acronym.toUpperCase() === s.toUpperCase();
13
```

acronym += word[0]; // Append the first character of the current word

// This method checks if the first characters of the words in the vector

// form the string 's', effectively checking if 's' is an acronym of 'words'.

# Time and Space Complexity

The time complexity of the given code snippet can be analyzed as follows: • There is a list comprehension that iterates through each word in the list words. This operation takes O(n) time, where n is the

number of words in the list.

Time Complexity

- For each word, we are accessing the first character w[0], which is an O(1) operation. • The join operation itself takes 0(m), where m is the total number of characters in the final acronym string, which in this case is
- Therefore, the total time complexity of the given function is O(n), since both iterating through the words and joining the characters are linear operations with respect to the number of words.

the same as the number of words n since we are only considering the first character of each word.

- Space Complexity
  - The list comprehension creates a temporary list that holds the first character of each word, which requires O(n) space, where n is the number of words.

The space complexity of the given code snippet can be analyzed as follows:

 The acronym string created by the join operation also requires O(n) space. Considering this, the total space complexity of the function is O(n), the space needed to create the temporary list and the acronym
