337. House Robber III

Depth-First Search

Tree

Problem Description

Medium

In this problem, you're given a binary tree that represents houses in a neighborhood. The root of the tree is the main entrance. Each house in this neighborhood is connected to one parent house and to two child houses, except for the leaf houses which do not have any child houses. This setup forms a binary tree structure. The goal is to calculate the maximum amount of money a thief can steal

Binary Tree

Dynamic Programming

without alerting the police. The catch is that the thief cannot rob two directly-linked houses on the same night because this would trigger an alarm and alert the police. Intuition

The intuition behind the solution is to use a <u>depth-first search</u> (DFS) technique and <u>dynamic programming</u> to explore all possible

combinations and make the optimal choice at each house (or node). We perform DFS to reach the bottom of the tree and then make

Robbing a house means we cannot rob its children, but we can rob its grandchildren.

There are a few points we should consider to understand the solution:

The solution uses a helper function, dfs(root), which returns two values for each house: the maximum amount of money obtained by

We should not rob two adjacent houses (in the way of the <u>tree</u> connections).

our way up, deciding at each step whether it's more profitable to rob the current house or not.

robbing the house (root.val) and not robbing the house. Therefore, for each node, we have two scenarios:

to the total (root.val + lb + rb). 2. We do not rob the current house and hence we take the maximum amounts that we can obtain whether we robbed or did not rob each of its children (max(la, lb) + max(ra, rb)).

1. We rob the current house and therefore add its value to the total amount and can only add the values of not robbing its children

- At each step, we make the decision that gives more money. We accumulate these decisions to calculate our final answer. The efficiency of this approach lies in the fact that we're only visiting each node once and computing the optimal outcome at each node
- using the results from its children. **Solution Approach**

in the rob function: 1. Define the recursive function dfs inside the rob function. The dfs function takes a node (root) from the binary tree as its parameter.

The solution makes use of a bottom-up approach to dynamic programming. Here's a step-by-step breakdown of the algorithm used

using max(la, lb) + max(ra, rb).

that can be robbed without alerting the police.

2. The dfs function returns a tuple (int, int) that contains two values: • The first value is the maximum amount of money that can be robbed if the current house is robbed this night.

• The second value is the maximum amount if the current house is not robbed this night. 3. When dfs is called on a None node (an empty subtree), it returns (0, 0) since there's nothing to rob.

4. When dfs is called on a non-empty node, it first calls itself recursively for both the left child (root.left) and right child

- (root.right). These recursive calls return the best possible outcomes for robbing/not-robbing from the left and right subtrees. Let's denote these returns as (la, lb) for the left subtree and (ra, rb) for the right subtree.
- 5. With these results from the left and right children, it calculates what would happen if we rob the current house. If we rob the current house (root.val), we can't rob its direct children due to the problem's constraints but we can add what we could rob

from the grandchildren (or next level down). So we create a value root.val + lb + rb.

7. The final return statement of the dfs function returns the tuple with these two values, which gets passed up the tree. 8. Finally, the rob function initiates this process by calling dfs(root) - starting the recursive calculation from the root of the binary

tree. It then returns the maximum of the two values returned by the dfs call, which represents the maximum amount of money

6. If we don't rob the current house, we can take the best outcomes from robbing or not robbing its children. We determine this

At the end of this recursive process, the solution has efficiently computed the optimal choice (to rob or not to rob each house) at every step without needing to check all possible combinations explicitly.

This algorithm is efficient because each node is visited only once due to the recursive nature of DFS, and the decision at each node

results of subproblems, preventing redundant calculations. Example Walkthrough

Let's illustrate the solution approach with a small example binary tree of houses where the values represent the money in each

is made using already-computed information from its children. The use of dynamic programming enables us to store and use the

3. Starting with the left child (value 2), it's not a leaf and has one right child (value 3). The 'dfs' function calls on this right child,

∘ If we rob this house, we can only add what we could rob from its grandchild (0) since it's a leaf. Hence, 2 + 0 = 2 for

2. The 'dfs' function is then recursively called on the left child (house with value 2) and the right child (house with value 5).

calculations:

Python Solution

self.val = val

self.left = left

self.right = right

4. For the left child (value 2), we now decide:

6. For the right child (value 5), the decision is:

Therefore, the 'dfs' call for the root returns (3, 7).

def __init__(self, val=0, left=None, right=None):

def rob(self, root: Optional[TreeNode]) -> int:

def dfs(node: Optional[TreeNode]) -> (int, int):

Helper function to perform depth-first search on the tree.

without including the current node's left child.

left_with_root, left_without_root = dfs(node.left)

without including the current node's right child.

right_with_root, right_without_root = dfs(node.right)

41 # Note: The Optional[TreeNode] type hint requires importing Optional from typing.

including the current node's right child.

return with_current, without_current

return max(dfs(root))

If the current node is None, return a tuple of zeros.

left_without_root is the maximum amount that can be robbed

right_without_root is the maximum amount that can be robbed

When robbing the current node, we cannot rob its children.

right_with_root is the maximum amount of money that can be robbed

Start DFS from the root and calculate the maximum amount that can be robbed.

// Base case: If the current node is null, return 0 for both cases.

// Not robbing the current node (taking the max of robbing or not robbing children)

// An array of two elements corresponding to robbing or not robbing the current node

int notRobNode = Math.max(leftResults[0], leftResults[1]) + Math.max(rightResults[0], rightResults[1]);

Recursively calculate the values for the right subtree.

So, the 'dfs' call for the left child (value 2) returns (2, 0).

robbing the house.

house:

o If we don't rob the house, we take the best of robbing or not robbing the grandchild (which are both 0). Therefore, not robbing yields max(0, 0) = 0.

The rob function starts by calling the dfs function on the root of the tree. Let's walk through the process:

which is a leaf. The call returns (0, 0) since there are no further children.

1. The 'dfs' function is called on the root node (house with value 3). This node is not a leaf and it has two children.

5. Moving on to the right child (value 5), it's also not a leaf and has one right child (value 1). The 'dfs' function is called on this right child, which is a leaf, and it returns (0, 0).

7. Now, we're back at the root house (value 3). We have the figures for robbing/not robbing its children, so we make our

 \circ If we rob the house, we add its value to what we could rob from its grandchild (0), hence 5 + 0 = 5. \circ If we don't rob the house, we consider the grandchild and get $\max(0, 0) = 0$. Thus, the 'dfs' call for the right child (value 5) returns (5, 0).

• If we rob the root house, we can't rob its children, but we can include what we could get from its grandchildren. Thus, we

∘ If we don't rob the root, we look at the best results from its children and combine those: max(2, 0) + max(5, 0) = 2 + 5 = 7. Normally we would have different numbers to consider here if the children were robbed or not, but in our case, the values

have 3 + 0 (from not robbing left child) + 0 (from not robbing right child) = 3.

are the same since the grandchildren nodes are leaves (hence giving 0).

means the maximum amount of money the thief can steal without alerting the police is 7.

This small example showcases the essence of the algorithm. The recursive nature of the 'dfs' function allows for an efficient and elegant bottom-up approach, only visiting each node once but always making the optimal decision based on the precomputed outcomes of its children.

8. Finally, the 'rob' function takes the maximum of the two values from the root's 'dfs' return value, which is max(3, 7) = 7. This

if node is None: return 0, 0 # Recursively calculate the values for the left subtree. 16 # left_with_root is the maximum amount of money that can be robbed # including the current node's left child.

Return a tuple of the maximum amount of money that can be robbed with and without the current node.

```
30
               with_current = node.val + left_without_root + right_without_root
31
32
               # When not robbing the current node, we can choose to rob or not rob each child independently.
33
               without_current = max(left_with_root, left_without_root) + max(right_with_root, right_without_root)
34
```

// Perform the DFS on the root and return the maximum of the two scenarios:

N and is not constant, O(H) is the more accurate representation of the space complexity.

* money you can rob without robbing any two directly-connected houses.

* that can be robbed without directly robbing two connected nodes.

* @param {TreeNode | null} node - The current node being visited.

function performDfs(node: TreeNode | null): [number, number] {

* @param {TreeNode | null} root - The root of the binary tree.

* is the maximum when the current node is excluded.

function rob(root: TreeNode | null): number {

// robbing or not robbing the root node.

return Math.max(...performDfs(root));

<u>Time and Space Complexity</u>

* @returns {number} The maximum amount of money that can be robbed.

The time complexity of the given code is O(N), where N is the number of nodes in the binary tree. This is because the dfs function is called exactly once for each node in the tree. During each call to dfs, it performs a constant amount of work (one addition, and a few comparisons) beside the recursive calls to the left and right children. Thus, the total work done is directly proportional to the number

Space Complexity The space complexity is O(H), where H is the height of the binary tree. This accounts for the call stack used during the depth-first search. In the worst-case scenario (a skewed tree), the height of the tree can become N, resulting in a space complexity of O(N). For

a balanced tree, the height H is log(N), so the space complexity would be O(log(N)). However, since H is always less than or equal to
