Problem Description

You are provided with the root of a binary tree, where each node contains a certain number of coins (node. val). The total number of coins in the tree is equal to the total number of nodes (n). Your task is to redistribute the coins so that every node has exactly one coin. Redistribution is done by moving coins between adjacent nodes (where adjacency is defined by the parent-child relationship). On each move, you can take one coin from a node and move it to an adjacent node. This problem asks you to find the minimum

number of moves required to achieve a state where every node has exactly one coin.

## Intuition

The number of moves for a single node is the number of excess coins it has or needs. When a node has more coins than it needs (more than 1), the excess can be moved to the parent. Conversely, if it needs coins (has less than 1 coin), it requests coins from its parent. To compute the number of moves, call the function recursively on the left and right children. The number of moves required for the

left subtree is the absolute value of extra/deficit coins in the left subtree and similarly for the right subtree. The current balance of

The intuition behind the solution is to use a post-order traversal, which visits the children of a node before visiting the node itself.

coins for the node is the node's value plus the sum of moves from left and right (which can be positive, negative, or zero) minus one coin that is needed by the node itself. If this balance is positive, it means the node has extra coins to pass up to its parent. If it's negative, it needs coins from its parent. The total number of moves is accumulated in a variable, which is the sum of the absolute values of extra/deficit coins from both subtrees. This approach works because it ensures that at each level of the tree, we move the minimum necessary coins to balance out the

Solution Approach

## Here's a step-by-step walkthrough of the implementation:

1. Define a nested helper function, dfs, which will perform the DFS traversal. This function accepts a single argument: the current

The solution uses a depth-first search (DFS) approach to traverse the binary tree and calculate the balance of coins at each node.

node being visited (initially the root of the tree). 2. The base case of the recursion is to return of if the root passed to the function is None, which means you've reached a leaf node's

children before considering the parent. This ensures we don't make redundant moves.

- nonexistent child. 3. Recursively call dfs on the left child of the current node and store the result in left, which represents the number of excess or
- deficit coins in the left subtree. Do the same for the right child and store the result in right.
- 5. The main logic of the solution is encapsulated in these two points: The total number of moves required (ans) is increased by abs(left) + abs(right). This represents the total number of
- moves needed to balance the left and right subtrees of the current node.
- The dfs function returns left + right + root.val 1. This return value represents the balance of the current node after accounting for its own coin (root.val), and it's meant to be either passed up to the parent (if positive) or requested from the
- parent (if negative). 6. The ans variable is defined in the outer function scope but is modified inside the dfs function. This is done using the nonlocal keyword, which allows the inner function to modify ans that is defined in the non-local (outer) scope.
- 7. Initialize ans to 0 before starting the DFS. This variable will accumulate the total number of moves required to balance the tree. 8. After the DFS completes, and contains the total number of moves, and the function returns this value.
- The algorithm efficiently calculates the required number of moves using a post-order traversal (visit children first, then process the

current node), which helps to avoid redundant moves. It does not require any additional data structures beyond the function call

Example Walkthrough

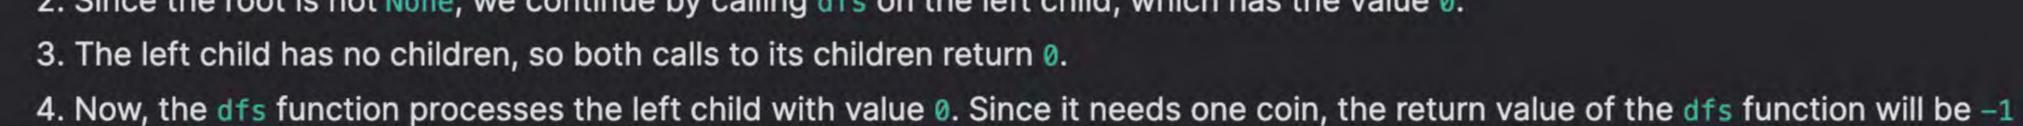

Let's take a simple binary tree as an example to illustrate the solution approach. Consider this binary tree with 3 nodes:

# Here 3, 0, and 0 are the values at each node, respectively, indicating the number of coins they hold. We need to redistribute these

stack used for recursion.

coins such that each node has exactly one coin.

2. Since the root is not None, we continue by calling dfs on the left child, which has the value 0.

for this node. 5. Similarly, dfs is called on the right child, which also has the value 0, and the process is the same as the left child. The return value is -1.

6. With both children processed, we come back to the root node. We use the return values from the left and right child (-1 from

minimum number of moves required to redistribute the coins.

def \_\_init\_\_(self, val=0, left=None, right=None):

left\_balance = dfs(node.left)

right\_balance = dfs(node.right)

def distributeCoins(self, root: Optional[TreeNode]) -> int:

private int totalMoves; // To track the total number of moves needed

totalMoves = 0; // Initialize the total moves to 0

public int distributeCoins(TreeNode root) {

// Distributes coins in the binary tree such that every node has exactly one coin

postOrderTraversal(root); // Start post-order traversal from the root

return totalMoves; // After traversal, totalMoves has the answer

1. Starting at the root, the dfs function is called on the root node which has the value 3.

- each) to calculate the number of moves required for the root.
- (which is our goal for every node), it needs no further action. 9. The ans variable gets updated in each recursive call, and after the entire tree is traversed, it holds the value 2, which is the

8. The current balance for the root node after these moves is 3 + (-1) + (-1) - 1 = 0. Since the root now has exactly 1 coin

7. The total moves at the root node are abs(-1) + abs(-1) = 2. This is because we need to move one coin to each child.

Finally, after the DFS traversal finishes, we find that the minimum number of moves required for this example is 2. **Python Solution**
