884. Uncommon Words from Two Sentences

Problem Description

The given problem involves finding words that are unique to each of two separate sentences. In more detail, a 'sentence' is defined as a string of words, with each word being separated by a single space and consisting only of lowercase letters. A word is deemed 'uncommon' if it satisfies two requirements: firstly, it must appear exactly once within either sentence; secondly, it must not appear in the other sentence at all.

To solve this problem, we are tasked with comparing two distinct sentences, identified as s1 and s2. The goal is to curate a list

containing all such 'uncommon' words. The solution does not require the words to be in any particular sequence, implying that the words can be listed in any order. The core challenge lies in devising an efficient method to distinguish which words appear only once in either sentence and do not show up in the other.

To arrive at the solution for identifying uncommon words from two sentences, consider a straightforward approach: counting the

Intuition

The Python Counter class from the collections module simplifies this task. It allows us to count the frequency of elements within an iterable, such as a list of words. Therefore, the first step is to split each sentence into a list of words using the split() method, which naturally separates the sentence according to spaces. Applying Counter to these lists provides a dictionary-like

checking if its total count is exactly one, signifying it appears only once and isn't shared between the two sentences.

occurrences of each word across both sentences. By combining the counts, we can determine if a word is uncommon by

object where keys are the words and values are their respective counts.

The next step is to combine these counts. The + operator merges the two Counter objects in a way that adds up the counts for common words between s1 and s2. This merged counter now holds the total frequency of every word in both sentences.

The final step is straightforward: iterate over the items in the combined counter and select the words (s) where the associated

count (v) is exactly one. These words are the 'uncommon' words which need to be returned. Using list comprehension makes this step concise and efficient, resulting in a one-liner solution that fetches the required list of uncommon words.

Solution Approach

The solution uses the Counter data structure from Python's collections module to implement the approach efficiently. Here's how the implementation breaks down:

Split the sentences into words: The first step is to split s1 and s2 into individual words based on spaces. This is done using

Python's built-in split() method: words s1 = s1.split()

counter_s2 = Counter(words_s2)

or present in both sentences.

the sum of word counts from both sentences:

words_s2 = s2.split()

After this step, words_s1 and words_s2 are lists that contain all the words from s1 and s2, respectively.

2. Count the word occurrences: Next, we create two Counter objects for these lists:

counter_s1 = Counter(words_s1)

```
Here, counter_s1 and counter_s2 act like dictionaries where each word is a key, and its count in the corresponding sentence is the value.
```

Combine the counters: By adding these two Counter objects using the + operation, we obtain a single counter that contains

In combined_counter, any word with a total count greater than 1 indicates that it is either repeated within the same sentence

combined_counter = counter_s1 + counter_s2

uncommon_words = [word for word, count in combined_counter.items() if count == 1]

count == 1), and if so, the word is added to the list uncommon_words.

def uncommonFromSentences(self, s1: str, s2: str) -> List[str]:

Step 3 and 4: combine counts and filter uncommon words

return [word for word, count in cnt.items() if count == 1]

Step 1 and 2: count word occurrences

s1: "apple banana" s2: "banana orange apple"

Counter({'apple': 2, 'banana': 2, 'orange': 1})

Combine the word counts from both sentences

// Create a Hash Map to store word counts

for (String word : s2.split(" ")) {

if (entry.getValue() == 1) {

Find and return the list of words that appear only once

public String[] uncommonFromSentences(String s1, String s2) {

// List to hold the words that occur exactly once

List<String> uniqueWords = new ArrayList<>();

// Iterate through the entry set of wordCounts

uniqueWords.add(entry.getKey());

// Return the unique words as an array of strings

return result; // Return the list of uncommon words

// exactly once in either of the two sentences

const uncommonWords: string[] = [];

uncommonWords.push(word);

// Return the array of uncommon words

if (count === 1) {

return uncommonWords;

from typing import List

class Solution:

Time Complexity

s1 and s2.

from collections import Counter

const wordCounts: Map<string, number> = new Map();

// This function takes two sentences as input and returns an array of words that appear

function uncommonFromSentences(sentence1: string, sentence2: string): string[] {

// Split both sentences into words and combine them into a single array

for (const word of [...sentence1.split(' '), ...sentence2.split(' ')]) {

// Then iterate over the array to count the occurrences of each word

// Array to store the uncommon words (words that appear exactly once)

// Iterate over the wordCounts map to find words with a count of 1

// These are the words that are unique to either sentence

for (const [word, count] of wordCounts.entries()) {

wordCounts.set(word, (wordCounts.get(word) || 0) + 1);

// Create a map to keep track of word counts across both sentences

return uniqueWords.toArray(new String[0]);

Following the solution approach:

cnt = Counter(s1.split()) + Counter(s2.split())

```
Filter out the uncommon words: Finally, we need to gather only those words that appear exactly once – which implies they're uncommon:
```

The full implementation of the function uncommonFromSentences as a method inside the Solution class is as follows: class Solution:

This list comprehension iterates over the items of combined_counter. For each word, it checks if the count is 1 (using if

```
solution efficiently identifies all uncommon words with minimal code and avoids the need for handcrafting frequency calculations or manual comparisons between word lists.

Example Walkthrough

Let's consider two sentences as examples:
```

In conclusion, by utilizing the Counter data structure to perform frequency analysis and array comprehensions for filtering, the

Split the sentences into words: For s1: words_s1 = ['apple', 'banana'] For s2: words_s2 = ['banana', 'orange', 'apple']
 Both sentences are split into lists of individual words.

Count the word occurrences: Here's what the Counter objects might look like: counter_s1 = Counter({'apple': 1,

Each word is now associated with its occurrence count in the sentences. 3. **Combine the counters**: When combined, the counters reflect the total occurrence of each word: combined_counter =

Solution Implementation

Python

Java

C++

};

TypeScript

#include <vector>

#include <string>

#include <sstream>

#include <unordered_map>

class Solution:

class Solution {

This shows 'apple' and 'banana' each have a total count of 2, while 'orange' has a count of 1.

4. Filter out the uncommon words: We want the words which have a count of exactly 1: uncommon_words = ['orange']

Thus, with our example, the function uncommonFromSentences(s1, s2) would return ['orange'] as the list of uncommon words.

Only 'orange' fulfills the criteria of being uncommon (appearing exactly once overall and not in both sentences).

from collections import Counter from typing import List

def uncommonFromSentences(self, sentence1: str, sentence2: str) -> List[str]:

combined_counts = Counter(sentence1.split()) + Counter(sentence2.split())

return [word for word, count in combined_counts.items() if count == 1]

wordCounts.put(word, wordCounts.getOrDefault(word, 0) + 1);

wordCounts.put(word, wordCounts.getOrDefault(word, 0) + 1);

for (Map.Entry<String, Integer> entry : wordCounts.entrySet()) {

// If a word count is exactly 1, it's uncommon, add to the list

// Split the second string by spaces and count the occurrences of each word

'banana': 1}) counter_s2 = Counter({'banana': 1, 'orange': 1, 'apple': 1})

Map<String, Integer> wordCounts = new HashMap<>();
// Split the first string by spaces and count the occurrences of each word
for (String word : s1.split(" ")) {

```
using namespace std;
class Solution {
public:
   vector<string> uncommonFromSentences(string A, string B) {
       // Map to store the count of each word across both sentences
       unordered_map<string, int> wordCount;
       // Lambda function to parse each word in a sentence and update the word count
       auto addWordsToCount = [&](const string& sentence) {
            stringstream stream(sentence);
            string word;
           while (stream >> word) {
               ++wordCount[word]; // Increment the word count for each word found
       // Parse both sentences A and B to count the words
       addWordsToCount(A);
       addWordsToCount(B);
       // Vector to store the result – the uncommon words from both sentences
       vector<string> result;
       // Iterate through the word count map
        for (const auto& entry : wordCount) {
           // If the word count is 1, that means it's an uncommon word
           if (entry.second == 1) {
               // Add it to the result list
               result.emplace_back(entry.first);
```

def uncommonFromSentences(self, sentence1: str, sentence2: str) -> List[str]:
 # Combine the word counts from both sentences
 combined_counts = Counter(sentence1.split()) + Counter(sentence2.split())

Find and return the list of words that appear only once
 return [word for word, count in combined_counts.items() if count == 1]

2. The creation of two Counter objects from the split results of s1 and s2: The Counter object creation from a list of words has a time complexity of O(K1 + K2), where K1 is the number of words in s1 and K2 is the number of words in s2. It counts the frequency of each word.

Time and Space Complexity

number of unique words across both s1 and s2. The list comprehension that follows iterates through the combined Counter object, which also has a complexity of O(U).

The time complexity of the provided code mainly involves three steps:

the length of s2. The split() method goes through each character in the strings.

Space Complexity

The splitting of strings s1 and s2: This operation has a time complexity of O(N + M), where N is the length of s1 and M is

Adding two Counter objects and filtering for uncommon words: The addition of two Counter objects is O(U), where U is the

Thus, the overall time complexity of the code is O(N + M + U), where $U \ll K1 + K2$ since U is the count of unique words in both

- The space complexity is determined by:

 1. The lists created from splitting s1 and s2: This depends on the number of words in s1 and s2, which is 0(K1 + K2).
- The Counter objects for s1 and s2: This also depends on the number of unique words, which would be 0(U).
 The final list of uncommon words: In the worst-case scenario, all words are uncommon, which would also result in 0(U) space complexity.

Since $U \ll K1 + K2$, the overall space complexity can be described as O(K1 + K2).
