2787. Ways to Express an Integer as Sum of Powers

**Problem Description** 

**Dynamic Programming** 

Medium

many different ways we can find sets of unique positive integers [n1, n2, ..., nk] such that when each number ni is raised to the power of x and then all of these xth powers are added together, the sum equals n. The final result must be returned modulo 10^9 + 7 to manage large numbers. For a given number n = 160 and x = 3, an example of such a representation is  $160 = 2^3 + 3^3 + 5^3$ . However, the problem asks for the count of all possible such representations, not just one.

The objective of this problem is to find the total number of unique ways we can represent a given positive integer n as a sum of

the xth powers of distinct positive integers. In other words, for two positive numbers n and x, we need to figure out in how

Intuition

The intuition behind the solution is to use dynamic programming to keep track of the number of ways we can form different sums

### using xth powers of numbers up to i. We define a 2-dimensional array f where f[i][j] will store the number of ways we can form the sum j using the xth power of integers from 1 to i.

To populate this array, we'll start with the understanding that there's exactly one way to achieve a sum of 0 (by using no numbers), so f[0][0] = 1. Then, we iterate over each number from 1 to n, calculating its xth power (k = pow(i, x)) and updating the f array. For each i, we iterate through all possible sums j from 0 to n, and we do the following:

• We first set f[i][j] to f[i-1][j], which represents the number of ways to get a sum j without using the ith number. • If k (the xth power of i) is less than or equal to j, it means we can include i in a sum that totals j. Therefore, we add the number of ways to get the remaining sum (j - k) using integers up to i - 1. That is, f[i][j] += f[i-1][j - k]. • Every time we update f[i][j], we take the result modulo 10^9 + 7 to keep the number within bounds.

- At the end of the iterations, f[n][n] will hold the total number of ways we can represent n using the xth powers of unique integers, and this is what we return.
- Solution Approach

doing something. To tackle this particular problem, we create a two-dimensional list f that serves as our DP table. This table has dimensions  $(n+1) \times (n+1)$  where n is the input integer whose expressions we need to find.

The solution uses dynamic programming, a method often used to solve problems that involve counting combinations or ways of

The idea is to gradually build up the number of ways to reach a certain sum j using xth powers of numbers up to i. Let's take a

## We start by initializing our DP table, f, with zeros and setting f[0][0] to 1, as there's only one way to have a sum of 0 (using

none of the numbers).

closer look at how the code implements this:

f[i][j] = (f[i][j] + f[i - 1][j - k]) % mod

Finally, the solution function returns this count:

[1, 0, 0, 0, 0, 0, 0, 0, 0, 0],

[0, 0, 0, 0, 0, 0, 0, 0, 0, 0],

... (up to f[10][0] which are all zeros)

 $f[1][1] = f[0][1] + f[0][0] = 1 (only using 1^2)$ 

 $f[2][4] = f[1][4] + f[1][0] = 1 (using 2^2)$ 

 $f[2][5] = f[1][5] + f[1][1] = 1 (using 1^2 and 2^2)$ 

 $f[2][10] = f[1][10] + f[1][6] = 1 (using 1^2 and 3^2)$ 

def numberOfWays(self, total sum: int, exponent: int) -> int:

# Initializing a dynamic programming table where

# of i-th powers of first i natural numbers.

# Iterate over all numbers from 1 to total\_sum

# Calculate the i-th power of the number

# powers of the first total sum natural numbers.

for i in range(1, total sum + 1):

for i in range(total sum + 1):

power = pow(i, exponent)

return dp[total\_sum][total\_sum]

\* @param n The target sum we want to achieve.

// using powers of numbers from 1 to `i`

for (int i = 0; i <= n; ++i) {

if (powerOfI <= i) {</pre>

function numberOfWays(n: number, x: number): number {

const ways = Array.from({ length: n + 1 }, () =>

Array(n + 1).fill(0);

// after dividing by this large prime.

// Iterate over each number from 1 to n.

// The answer is the number of ways to write n

def numberOfWays(self, total sum: int, exponent: int) -> int:

# Initializing a dynamic programming table where

# Modulo constant to prevent overflow issues for large numbers

// using powers of all numbers up to n.

return ways[n][n];

MOD = 10 \*\* 9 + 7

class Solution:

const MODUL0 = 10 \*\* 9 + 7;

ways[0][0] = 1;

// Modulo constant for the result as we only need the remainder

// Creating a 2D array 'ways' of dimensions (n+1)x(n+1) to store

// the number of ways to write numbers as the sum of powers of x.

// Base case: there is only one way to write 0 - as an empty sum.

**}**;

**TypeScript** 

dp[i][j] = dp[i - 1][j];

public int numberOfWays(int n, int x) {

final int MOD = (int) 1e9 + 7;

\* @param x The power to which we will raise numbers.

# Modulo constant to prevent overflow issues for large numbers

# dp[i][i] represents the number of ways to write j as a sum

 $dp = [[0] * (total_sum + 1) for _ in range(total_sum + 1)]$ 

# Iterate over all possible sums from 0 to total\_sum

\* This method calculates the number of ways to reach a target sum `n`

\* @return The number of ways to achieve the target sum using the powers.

\* using unique powers `x` of the numbers from 1 to `n` inclusive.

// Define the modulo constant to prevent overflow issues

// Initialize a 2D array to store intermediate results

// f[i][i] will store the number of ways to reach the sum `j`

as 4<sup>2</sup> already exceeds 10, and higher powers won't be considered.

return f[n][n]

of x.

f = [

**Python** 

Java

class Solution {

**/**\*\*

\*/

class Solution:

MOD = 10 \*\* 9 + 7

dp[0][0] = 1

 $f = [[0] * (n + 1) for _ in range(n + 1)]$ f[0][0] = 1We then iterate through each number i from 1 to n, since we are considering sums of numbers raised to the power x. And

for each number, we calculate its xth power and store it in k. for i in range(1, n + 1): k = pow(i, x)

```
using i. This is obtained from f[i - 1][j].
for j in range(n + 1):
   f[i][j] = f[i - 1][j]
```

For each i, we then go through all possible sums j. We set f[i][j] to the number of ways to form the same sum j without

```
If the xth power of i(k) is less than or equal to j, we find the number of ways to make up the remaining value (j - k) with
 the previous numbers. We then add this count to our current count of ways for sum j.
if k <= i:
```

The % mod ensures that the resulting count is within the bounds set by the problem statement.

```
By the end of these iterations, f[n] [n] contains the desired count of ways to express n as a sum of the xth power of unique
positive integers. Because we iterated over all numbers from 1 to n and for each considered all subsets of these numbers and
ways to sum up to j, our final count is comprehensive.
```

```
By systematically adding the ways to form smaller sums and building up to the larger sums, the dynamic programming approach
eliminates redundant calculations, thus optimizing the process of finding all possible combinations that sum up to n using powers
```

Let's take a small example to illustrate the solution approach. Consider n = 10 and x = 2. We want to find out how many unique

Initialize the two-dimensional list, f, with zeros and set f[0][0] to 1. This represents the number of ways to represent 0 as

the sum of squares of numbers from 0. There is only one way, which is to use none of the numbers:

count for j-k from the previous iterations. This represents including number i in our sum.

Example updates for i = 1 and j = 1 to 10 (with modulo operation omitted for simplicity):

f[1][2] = f[0][2] + f[0][1] = 0 (can't express 2 as only square of 1)

f[1][10] = f[0][10] + f[0][9] = 0 (can't express 10 as only square of 1)

ways can we express n as a sum of squares of distinct positive integers.

```
We iterate through numbers i from 1 to n (1 to 10), and for each number, we compute its square (k = i^2).
Example for i = 1: k = 1^2 = 1
```

With k = 1 for i = 1, we iterate through sums j from 0 to n. If k (1 in this case) is less than or equal to j, we add the

```
We repeat step 3 for all i up to n. For instance, when i = 2, k = 2^2 = 4.
Example updates for i = 2:
```

As we continue this process and update f for increasing i and j, we eventually build up the count. By the time we reach

f[10][10], it will have been updated with all possible ways to express 10 as a sum of squares of unique integers from 1 to 3,

After evaluating f[i][j] with the above steps while including the necessary modulo operation, the answer for f[10][10] will

give us the total number of ways we can represent 10 using the squares of unique integers. In this case, the unique ways are

{1^2, 3^2} and {1^2, 2^2, 3^2} minus {2^2, 3^2} since 2^2 + 3^2 is greater than 10, giving us a final answer as 2.

```
Solution Implementation
```

# There is one way to form the sum 0 using 0 numbers: use no numbers at all.

```
# The number of ways to form the sum j without using the i-th number
        dp[i][i] = dp[i - 1][i]
        # If the power is less than or equal to the sum i, then
        # add the number of ways to form the previous sum j-power
        if power <= i:</pre>
            dp[i][j] = (dp[i][j] + dp[i - 1][j - power]) % MOD
# Return the number of ways to write total sum as a sum of
```

```
int[][] dp = new int[n + 1][n + 1];
       // There is exactly one way to reach the sum 0, which is by using no numbers
       dp[0][0] = 1;
       // Loop over every number up to `n` to compute the powers and the ways to reach each sum `j`
        for (int i = 1; i <= n; ++i) {

# The algorithm consists of a nested loop where the outer loop runs n times, and the inner loop also runs n times. In every

**Time Complexity** 

Time and Space Complexity

iteration of the inner loop, the algorithm performs constant-time operations, except for the pow(i, x) calculation, which is done once per outer loop iteration.

The pow function is typically implemented with a logarithmic time complexity concerning the exponent. However, since the

The given Python code defines a function <a href="mailto:number0fWays">number0fWays</a> that calculates the number of ways to reach a total sum in by adding

powers of integers up to n, each raised to the power of x. Below is an analysis of the code's time and space complexity:

exponent x is constant for the entire run of the algorithm, each call to pow will have a constant time complexity. Thus, we can consider the pow(i, x) part to have a time complexity of 0(1) for each iteration of i. Hence, the time complexity is primarily governed by the nested loop, resulting in a time complexity of  $0(n^2)$ .

**Space Complexity** 

The code uses a 2-dimensional list f with dimensions n + 1 by n + 1, which stores the computed values. This list is the primary consumer of memory in the algorithm.

The space complexity for the list f is  $O(n^2)$ , which reflects the amount of memory used with respect to the input size n.
