1725. Number Of Rectangles That Can Form The Largest Square

Leetcode Link Array

Problem Description

dimensions of the ith rectangle as a pair $[l_i, w_i]$ indicating its length l_i and width w_i .

In the given problem, we are presented with an array named rectangles, where each element rectangles [i] represents the

k is less than or equal to both the length and the width of the rectangle. For instance, from a rectangle [4,6], we can cut out a square with a maximum side length of 4.

We are allowed to make cuts to these rectangles in order to form squares. A square can be formed from a rectangle if its side length

count the number of rectangles in the array that are capable of forming a square with this maximum side length. To summarize, the task is to first determine the largest possible square side length that can be cut out from any of the rectangles,

The objective is to find the side length of the largest square, maxLen, that can be formed from these rectangles. Then we need to

and then to count how many rectangles in the list are large enough to provide a square of that size.

The solution involves a straightforward approach. Here's the process to understand how the solution works:

This value is stored in a temporary variable t.

process, and simultaneously counts the qualifying rectangles.

Intuition

1. Initialize two variables ans and mx to keep track of the count of rectangles that can produce the largest square, and to store the maximum square side length, respectively.

2. Traverse through each rectangle in the rectangles array and for each rectangle, determine the side length of the largest

possible square, which would be the minimum of the length and width of the rectangle as we are bound by the lesser dimension.

- 3. If we find a square side length t greater than the current mx, we know that we have found a new, larger square side length. So, we update mx to this new maximum side length t, and reset ans to 1 since this is the first rectangle that can form a square of side length t.
- 4. If t is equal to mx, it means the current rectangle can also form a square of the largest side length found so far. Therefore, we increment ans by 1 to reflect this additional rectangle.
- 5. If t is less than mx, we do nothing, as the rectangle cannot produce a square of side length maxLen. 6. Once all rectangles have been processed, ans will contain the final count of rectangles that can produce squares of side length
- This solution works well because it efficiently iterates through the list only once, determines the maximum square side length in the
- Solution Approach

The solution takes advantage of simple mathematical concepts and logical comparison within a single-pass for-loop to achieve the

Here's a step-by-step breakdown of the implementation details with reference to the solution code:

desired result.

mx, and we return ans.

the maximum square side length possible, also initially set to 0. 1 ans = mx = 0

2. We begin iterating over each rectangle provided in the rectangles list. Within the loop, we're performing the following steps for

1. Initialize two variables, and to store the number of rectangles that can form the largest square, initially set to 0, and mx to store

```
1 for l, w in rectangles:
```

each rectangle:

3. Calculate the largest possible square side length t from the current rectangle by taking the minimum of its length 1 and width w. This relies on the constraint that a square's side length must be less than or equal to the lengths of both sides of the rectangle. 1 t = min(l, w)

4. Compare the calculated square side length t with the maximum found so far, mx. If t is greater, we've discovered a new

```
maximum square size. We then update mx to this new value, and set ans to 1 since this is the first occurrence of such a large
```

mx, ans = t, 1

square.

1 if mx < t:

Hence we increment ans by 1 without changing mx. 1 elif mx == t: ans += 1

6. If t is less than mx, that indicates the current rectangle cannot contribute to a square of side length mx, so no operation is

5. If t equals the current maximum mx, it means another rectangle was found which can form a square of the same maximum size.

```
7. After the loop completes, the variable ans contains the count of rectangles which can form the largest square, and this value is
  returned.
```

1 return ans

performed.

- In terms of algorithms and data structures, this solution is a straight-forward linear scan (O(n) complexity) without the need for any additional complex data structures. The use of basic variables and a single for-loop makes the code efficient and easy to
- understand. This elegant simplicity arises from the observation that we're interested only in the counts related to the maximum square size which can be maintained and updated on-the-fly as we inspect each rectangle.

```
Example Walkthrough
```

square side length we can cut from any rectangle and then count how many rectangles can form a square of that size. 1. We initialize ans and mx to 0. These will keep track of the count and size of the largest square, respectively. 2. We begin iterating over each rectangle:

For the first rectangle [3, 5], the largest square side length t we can cut is min(3, 5) = 3. Since 3 is greater than the

Let's consider the following array of rectangles: rectangles = [[3, 5], [6, 6], [5, 2], [4, 4]]. We need to determine the largest

current mx (0), we update mx to 3 and set ans to 1. \circ Moving on to the second rectangle [6, 6], t = min(6, 6) = 6. This is greater than the current mx (3), so mx is updated to 6

and ans is reset to 1.

changes are made to mx or ans.

good_rectangles_count = 0

for length, width in rectangles:

side_length = min(length, width)

if side_length > max_square_length:

good_rectangles_count = 1

1 #include <vector> // Include necessary library for vector

2 #include <algorithm> // Include for access to the min function

max_square_length = side_length

increment the count of good rectangles

 \circ For the third rectangle [5, 2], t = min(5, 2) = 2. This is less than the current mx (6), so no changes are made to mx or ans. The last rectangle [4, 4] also provides a square with t = min(4, 4) = 4, which is still less than our mx (6), so again no

length and the count of rectangles that could form a square of that maximum size.

Loop through each rectangle to find the maximum square length

update max_square_length and reset good_rectangles_count

If the current square length is equal to the maximum,

Find the smaller of the two sides to get the largest possible square

If the current square length is greater than the previous maximum,

3. After completing the loop, mx is 6 and ans is 1, since only one rectangle, [6, 6], could produce a square with the largest possible side length. Hence, the function would return 1.

This example demonstrates the straightforward linear scan through the array and the simple tracking of the maximum square side

class Solution: def countGoodRectangles(self, rectangles: List[List[int]]) -> int: # Initialize maximum square length and count of good rectangles max_square_length = 0

elif side_length == max_square_length: 22 good_rectangles_count += 1 23 24 # Return the total count of rectangles that can produce the largest square 25 return good_rectangles_count

The time complexity of the given code is O(n), where n is the number of rectangles in the input list rectangles. This is because the

code iterates through each rectangle exactly once, and for each rectangle, it performs a constant number of operations: calculating

the minimum of the length and width, comparison, and possibly incrementing the answer or updating the maximum length of a

Time and Space Complexity

Time Complexity

square.

Space Complexity

The space complexity of the code is 0(1). This is because the code only uses a fixed amount of additional space: two variables (ans and mx). The amount of space used does not depend on the input size, so the space complexity is constant.
