617. Merge Two Binary Trees **Depth-First Search Breadth-First Search Binary Tree**

stacks create the entire tree level by level.

nothing to merge. If both nodes are null, the merged node is also null.

Problem Description

the resulting tree should have a node with that same value. To merge the trees, you must start from their root nodes and continue merging the subtrees recursively following the same rule.

You are asked to merge two binary trees in such a way that if two nodes from the two trees occupy the same position, their

values are summed together to create a new node in the resulting binary tree. If at any position, only one of the trees has a node,

Intuition To merge the two given binary trees, the solution employs a recursive approach. Each recursive call is responsible for handling the merging of two nodes – one from each of the trees. The first step is to determine what to do if one or both of the nodes being

merged are null. If one of the nodes is null, the other node (which is not null) can be used directly in the merged tree since there's

When both nodes are not null, a new node is created with a value that is the sum of the two nodes' values. Following that, the

recursion is applied to both the left and the right children of the nodes being merged to handle the full depth of the trees. Thus, the process creates a new tree that is the result of merging the input trees by summing the overlapping nodes and copying the non-overlapping nodes. Merging goes as deep as the deepest tree, and each level of recursion handles only one level of the tree. This way, the recursion

Solution Approach To implement the merging of two binary trees as described in the problem statement, the solution uses a recursive depth-first search algorithm.

Here's a step-by-step breakdown of the algorithm:

The base case of the recursive function handles the case when either root1 or root2 is None. If one of them is None, it

If both nodes are not None, it creates a new TreeNode with the sum of both nodes' values. This will be the current node in the

returns the other node, because there is nothing to merge. if root1 is None: return root2 if root2 is None:

- merged <u>tree</u>. node = TreeNode(root1.val + root2.val)
- To merge the left subtree of both trees, the function makes a recursive call with the left child of both root1 and root2 and assigns the return value to the left attribute of the new node. node.left = self.mergeTrees(root1.left, root2.left)

return root1

assigned to the right attribute of the new node. node.right = self.mergeTrees(root1.right, root2.right)

Similarly, to merge the right subtree, another recursive call is made with the right child of both nodes. The return value is

After recursively merging both the left and right subtrees, the function returns the node, which now represents the root of the

This depth-first recursive approach systematically merges all nodes at corresponding positions in each level of both input trees.

By continuously dividing the problem into smaller subproblems (merging the left and right children, respectively), the algorithm

The space complexity of this algorithm is O(n), where n is the smaller of the heights of the two input trees because it is the

maximum depth of the recursion stack. The time complexity is also O(n), where n in this case is the total number of nodes that

efficiently constructs the merged binary tree in a bottom-up manner, returning the merged root node as the result.

will be present in the new merged tree, as each node from both trees is visited exactly once.

the values of Tree 1's root (1) and Tree 2's root (2), giving us a root node with value 3.

merged tree's left child will inherit this right child directly.

5), which becomes the right child of the merged tree's root.

• Root node: Tree 1 has 1, Tree 2 has 2. The merged node has 3 (1 + 2).

Here is a step-by-step mapping of the decisions made to reach this merged tree:

• Left child of the root node: Tree 1 has 3, Tree 2 has 1. The merged node has 4 (3 + 1).

The merged binary tree now looks like this:

Solution Implementation

class TreeNode:

class Solution:

return node

merged subtree for the current recursive call.

Example Walkthrough Let's consider two simple binary trees to demonstrate the solution approach.

We want to merge Tree 1 and Tree 2 into a single tree. Following the step-by-step algorithm: Start at the root of both trees. Since none of them are None, we create a new root node for the merged tree with the sum of

Next, we merge the left children of both trees. Tree 1's left child has a value of 3 and Tree 2's left child has a value of 1.

Tree 2's left child also has a non-null right child with a value of 4. Tree 1 doesn't have a corresponding node here, so the

Merging the right children of the root nodes from Tree 1 and Tree 2 results in a new node with the sum of their values (2 + 3 =

Neither is None, so we create a new node with the sum of their values (3 + 1 = 4) which becomes the left child of the merged tree's root.

Tree 1:

Tree 2:

- Right child of root node: Tree 1 has 2, Tree 2 has 3. The merged node has 5 (2 + 3). • Right child of the left node: Tree 1 does not have a corresponding node, only Tree 2 has 4. The merged node has 4. This walkthrough illustrates how the recursive algorithm systematically combines the node values of overlapping positions while retaining the node values of non-overlapping positions from the given trees to construct a merged tree.
- merged_node = TreeNode(root1.value + root2.value) # Recursively merge the left children of both trees and assign to the left of the merged node. merged_node.left = self.mergeTrees(root1.left, root2.left)

class TreeNode { int value; // Variable to store the value of the node TreeNode left; // Reference to the left child node TreeNode right; // Reference to the right child node

       // Return the merged tree node
```

mergedNode->left = mergeTrees(firstRoot->left, secondRoot->left); // Recursively merge the right children. mergedNode->right = mergeTrees(firstRoot->right, secondRoot->right); // Return the root of the newly merged tree.

return mergedNode; **}**; **TypeScript** type TreeNodeOrNull = TreeNode | null; // Definition for a binary tree node. class TreeNode { val: number; left: TreeNodeOrNull; right: TreeNodeOrNull; constructor(val?: number, left?: TreeNodeOrNull = null, right?: TreeNodeOrNull = null) { this.val = val !== undefined ? val : 0; this.left = left; this.right = right; /** * Merges two binary trees into a new binary tree. * If two nodes overlap, the resulting node's value * is a sum of the overlapping nodes' values. * @param {TreeNodeOrNull} tree1 - The first binary tree. * @param {TreeNodeOrNull} tree2 - The second binary tree. * @returns {TreeNodeOrNull} - The merged binary tree. function mergeTrees(tree1: TreeNodeOrNull, tree2: TreeNodeOrNull): TreeNodeOrNull { // If both trees are null, return null. if (tree1 === null && tree2 === null) return null; // If one tree is null, return the other tree. if (tree1 === null) return tree2; if (tree2 === null) return tree1;

The provided code defines a method for merging two binary trees. The function mergeTrees takes two binary trees (root nodes root1 and root2) as input and returns a new binary tree that represents the sum of both input trees.

Return the merged tree root node.

Time Complexity: The time complexity of the function is O(n), where n is the number of nodes present in the smaller of the two trees. This is because the function visits each node from both the trees exactly once (in the worst case, when both trees are of the same size).

If the trees have a different number of nodes, the complexity is governed by the tree with fewer nodes since this is where the

Space Complexity:

recursion will stop for each path.

The space complexity is also 0(n), considering the worst-case scenario where the tree is completely unbalanced and resembles a linked list. In this case, n is again the number of nodes in the smaller tree. This is because the function will have a number of recursive calls on the stack proportional to the height of the tree, which, in the worst case, could be the number of nodes in the

tree if it's completely unbalanced. For a balanced tree, the space complexity would be $O(\log(n))$.

However, if we consider the space for the output tree, the space complexity would become 0(m+n), where m and n are the number of nodes in root1 and root2, respectively, since a new tree of size at most m+n is created. But often, the space used to create the output is not considered when analyzing the algorithm itself, since that space is required for the output data structure.
