2068. Check Whether Two Strings are Almost Equivalent

Hash Table Counting

Problem Description

The problem presents us with the concept of two strings, word1 and word2, being almost equivalent. Two strings are almost equivalent if for each letter in the alphabet, the number of times it appears in one word is within three of the number of times it appears in the other word. We are asked to write a function that takes two strings of equal length and returns true if they are almost equivalent, and false if they are not. This problem is essentially about comparing the frequency of each character from 'a' to 'z' in the two strings and checking if that frequency difference is at most 3.

Leetcode Link

Intuition

To solve this problem, the initial step is to understand that we need to count and compare the frequency of each letter in both strings. If the difference in the counts of any letter is more than 3, the strings are not almost equivalent.

The intuition behind the solution is to use a Counter data structure to store the frequencies of each letter from word1 and then decrement those frequencies based on the letters from word2. This way, we directly get the difference in frequencies between word1 and word2. By using the built-in Counter from Python's collections module, we can efficiently count the letter frequencies and easily compute the differences.

After processing both strings, we then check if all frequency differences are within the acceptable range (at most 3). The all() function is suitable for this check as it ensures that every letter satisfies the almost equivalent condition. If any letter's absolute frequency difference is greater than 3, all() immediately returns false, indicating that the words are not almost equivalent. Only if all frequency differences are within the allowed limit will all() return true, confirming that the strings are indeed almost equivalent.

comparison, making this a straightforward approach to solve the problem.

The solution is concise, and the use of the Counter and absolutes of the differences streamlines the entire process from counting to

In this solution, we're using the Counter data structure from Python's collections module, which is particularly useful for counting

Solution Approach

hashable objects (in this case, the characters of the strings). It internally maintains a dictionary where keys are the elements being counted and the values are their respective counts. Here's a breakdown of the steps in the algorithm:

1. We initialize the Counter with word1. This gives us a dictionary where each key is a unique character from word1, and its

- corresponding value is the number of times the character appears in word1. 2. We iterate through each character c in word2 and decrement the count of c in our Counter by 1. If c wasn't in word1, its count in
- the Counter will be -1, accurately reflecting the difference in frequency between word1 and word2. 3. After processing both strings, our Counter now represents the net frequency differences of each character.
- 4. The final step is to examine if all values (net differences) in the Counter are less than or equal to 3 in absolute value. This is
- achieved by using the all() function combined with a generator expression. The expression abs(x) <= 3 is evaluated for every value x in the Counter. If they all satisfy this condition, it means that the frequency of no character differs by more than 3 between the strings, hence word1 and word2 are almost equivalent, and the function returns true. If even one such condition fails, the function returns false as the strings are not almost equivalent. In terms of complexity:

The time complexity of the solution is O(N), where N is the length of the input strings. This is because we iterate over each string.

- once. The space complexity is O(1) despite using the Counter, as the size of the Counter is bounded by the number of unique
- This approach is efficient and exploits the constant upper bound on the number of unique characters. It elegantly simplifies the problem down to a single Counter check at the end.

Example Walkthrough

Step 1: Initialize the Counter with word1. This gives us a Counter object where each key is a character from word1, and the

1 Counter for word1: {'a': 1, 'b': 1, 'c': 1}

Let's consider word1 = "abc" and word2 = "bcd". We shall walk through the solution approach using these two words.

characters in word1, which is at most 26 in the English alphabet. Hence, it is a constant space overhead.

Step 2: Iterate through word2, decrementing the counts in the Counter by 1 for each character in word2.

```
1 Counter: {'a': 1, 'b': 0, 'c': 1}
```

After seeing 'b' in word2, decrement 'b' count by 1.

After seeing 'c' in word2, decrement 'c' count by 1.

corresponding value is the frequency of that character in word1.

1 Counter: {'a': 1, 'b': 0, 'c': 0}

1 Counter: {'a': 1, 'b': 0, 'c': 0, 'd': -1}

For character 'c': abs(0) <= 3 is True.

For character 'd': abs(-1) <= 3 is True.

def checkAlmostEquivalent(self, word1: str, word2: str) -> bool:

// Decrement the count for each character in word2

if (Math.abs(frequencyDifference) > 3) {

charFrequencyDifference[word2.charAt(i) - 'a']--;

for (int frequencyDifference : charFrequencyDifference) {

// Check if any character's frequency difference is greater than 3

// If the absolute frequency difference is greater than 3, return false

for (int i = 0; i < word2.length(); ++i) {</pre>

return false;

Decrement the count in the counter for each character in word2

return all(abs(frequency) <= 3 for frequency in char_counter.values())

Create a counter object to count the frequency of each character in wordl

• After seeing 'd' in word2, since 'd' is not in the Counter, its count becomes -1.

```
Step 4: Use the all() function with a generator expression to verify that all frequency differences are within 3. We check if abs(x)
3 for every value x in the Counter.
```

 For character 'a': abs(1) <= 3 is True. For character 'b': abs(0) <= 3 is True.

Since all conditions are True, all() returns True, hence word1 and word2 are almost equivalent and the function will return True.

Step 3: The Counter object now accurately reflects the difference in frequency for each character between word1 and word2.

```
This example clearly illustrates the solution approach – character counts are compared directly, and the process is both simple and
efficient.
```

char_counter = Counter(word1)

for character in word2:

Python Solution from collections import Counter

char_counter[character] -= 1 10 # Check if the absolute difference of each character's frequency is at most 3 # If it is within [-3, 3] inclusive for every character, the words are almost equivalent

class Solution:

```
16 # Example usage:
17 # sol = Solution()
18 # result = sol.checkAlmostEquivalent("abc", "pqr")
19 # print(result) # Output: True or False based on the words being almost equivalent
